Two points about the safe use of the auxiliary E-cylinder system should be noted. First, checking the E-cylinders is *not* part of an automatic machine checkout. The practitioner must manually open each cylinder and check the pressure gauges on the front of the machine. In the case of a two-tank oxygen manifold, the tanks must be serially opened and checked. The oxygen flush valve may be used to vent the pressure from the system after closing the first tank, so the pressure in the second tank can be accurately assessed. Second, it is imperative to keep the auxiliary E-cylinders closed during normal operation using pipeline gases because of the possibility of small leaks in the high-pressure system, or fluctuations in pipeline pressures allowing flow from the cylinder to be activated. An open oxygen cylinder may allow the anesthesiologist to be unaware of catastrophic pipeline failure. When the oxygen cylinder is closed, the immediate result of oxygen pipeline failure is a low oxygen pressure alarm. The auxiliary E-cylinder can then be opened, ensuring continued flow of oxygen to the patient while troubleshooting occurs. If the oxygen tank is *already open* when pipeline failure occurs, there may be only a subtle indication from the anesthesia machine that the oxygen source has

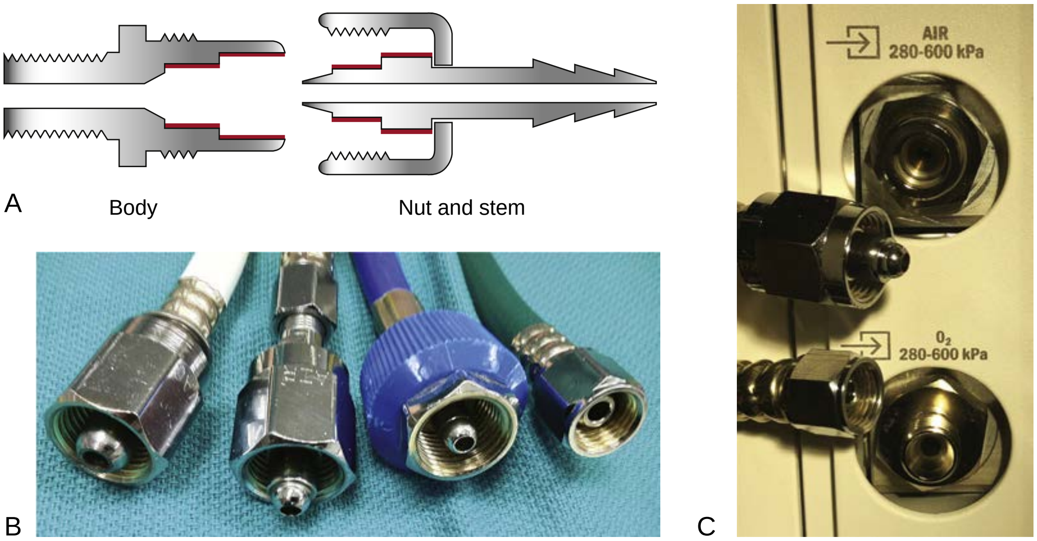

Fig. 22.4 Diameter Index Safety System. Diameter Index Safety System (DISS) connectors are used for noninterchangeable, removable medical gas connections at pressures less than 200 psig. They are also used for suction and waste gas connections. Indexing is accomplished through differing diameters of the connection components, resulting in key-like fitting when matched connectors come together. The oxygen connector is additionally distinguished from the other gas connectors by a unique threaded fitting diameter and a unique thread count. (A) DISS connector cross section. (B) Nut and stem connectors for (*left* to *right*) vacuum, air, nitrous oxide, and oxygen. (C) DISS connections at the back of an anesthesia workstation. (A, Modified from Yoder M. Gas supply systems. In: *Understanding Modern Anesthesia Systems*. Telford, PA: Dräger Medical; 2009.)

switched from pipeline to auxiliary tank. In this case, the low oxygen pressure alarm only occurs once the auxiliary tank has been depleted, nullifying the utility of the backup system.[12,19]

Intermediate-Pressure Section

Gas Pipeline Inlet: Central Gas Supply Source. Three gases are typically piped into the operating room by the hospital's central gas supply system: oxygen, air, and nitrous oxide. The main supply source of oxygen in a large hospital usually is a large cryogenic bulk oxygen storage system. These are refilled on site from a truck carrying liquid oxygen. Smaller hospitals may use liquid oxygen tanks that can be replaced rather than refilled on site, or even a bank of oxygen H-cylinders connected by a manifold. Oxygen storage systems must have backup supply and alarm systems in place.[14] Most hospitals use compressors to deliver cleaned, dried air to a pressurized reservoir for delivery to the pipeline system. Centrally supplied nitrous oxide arises either from a bank of H-type cylinders, or a bulk liquid storage system similar to that for oxygen.[14]

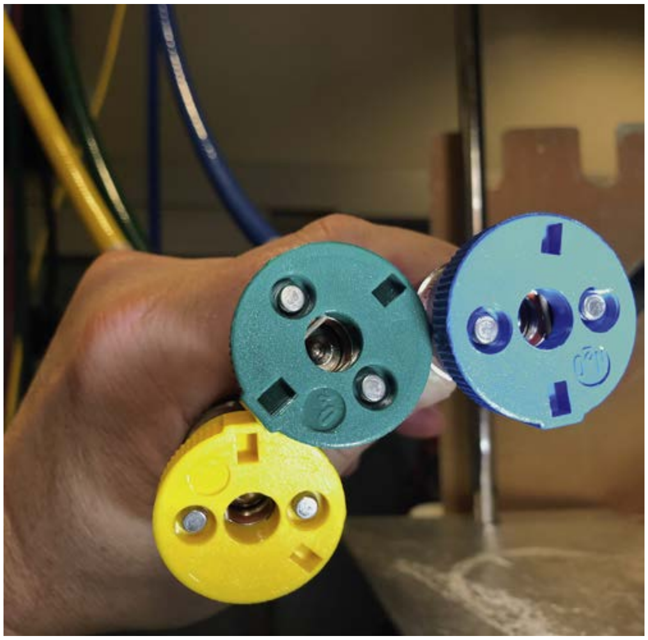

Fig. 22.5 Quick couplers. Quick couplers, like Diameter Index Safety System connectors, are used for noninterchangeable, removable medical gas, suction, and waste gas connections. Indexing is accomplished by the configuration of pins on one plate which match to recesses on the other plate (shown). The two plates lock together, allowing an airtight connection. A twist to the housing of the male plate allows the two plates to be disengaged.

The gas pipeline terminates in patient care areas of the hospital with one of two types of connector: the Diameter Index Safety System (DISS) connector system, or the quick coupler system. Within each type, the connectors for oxygen, air, and nitrous oxide are mutually incompatible, which helps to minimize the potential for connecting to the wrong gas. DISS connectors (as seen in Fig. 22.4) rely on matching diameters in the male and female connections to properly seat and thread the connection.[14,20] The quick couplers (Fig. 22.5) utilize pins and corresponding slots on the male and female ends, respectively, in order to ensure correct connections. Because these connectors can be plugged together or released with a simple twisting motion, they are especially appealing for equipment that needs to be moved between locations. In addition, in both systems the wall plates and hoses are color-coded for ease of identification.

The final medical gas pipeline connection to the anesthesia workstation is always through a DISS connector (Fig. 22.4C). Once the gas enters the machine, it encounters a filter followed by a pipeline check valve. This one-way valve prevents reverse flow of gas from the machine into the medical gas pipeline system or into the atmosphere from an open inlet. Interposed between the DISS inlet and the pipeline check valves is a sample port to measure pipeline oxygen pressure. The pipeline pressure must always be clearly visible on the front of the machine.

Oxygen Flush Valve. The oxygen flush valve is probably one of the oldest safety features on the machine and remains a machine standard today.[11,20,21] The oxygen flush valve allows manual delivery of a high flow rate of 100% oxygen directly to the patient's breathing circuit in order to overcome circuit leaks or to rapidly increase the inhaled oxygen concentration. Flow from the oxygen flush valve bypasses the anesthetic vaporizers (see Fig. 22.1). The intermediate-pressure segment of the gas supply system feeds the valve, which remains closed until the operator opens it. The feature is usually available even when the machine is not turned on because the valve is located upstream from the machine's pneumatic power switch. Flow from the oxygen flush valve enters the low-pressure circuit downstream from the vaporizers at a rate between 35 and 75 L/min, depending on the machine and operating pressure.[11,20,21]

Several hazards have been reported with the oxygen flush valve. A defective or damaged valve can stick in the fully open position and result in barotrauma.[22] Oxygen flow from a valve sticking in a partially open position or overzealous oxygen flushing can dilute the inhaled anesthetic agent concentration, potentially resulting in awareness under anesthesia.[23,24,24a] Oxygen flushing during the inspiratory phase of positive-pressure ventilation can produce barotrauma if the anesthesia machine does not incorporate a fresh gas decoupling feature or an appropriately adjusted inspiratory pressure controller. Fresh gas decoupling prevents the fresh gas inflow from either the flowmeters or the oxygen flush valve from increasing the delivered ventilator tidal volume presented to the patient's lungs (see section on fresh gas flow compensation and fresh gas decoupling). With most older anesthesia breathing circuits, excess volume could not be vented during the inspiratory phase of mechanical ventilation because the ventilator relief valve was closed and the breathing circuit adjustable pressure-limiting (APL) valve was either out of circuit or closed.[25]

Although the oxygen flush valve can potentially provide a high-pressure, high-flow oxygen source at the machine's fresh gas outlet suitable for jet ventilation, it has potential limitations. In some machines, the fresh gas outlet is no longer easy to access, and not all machines are capable of generating pressures at the outlet that are sufficient to deliver jet ventilation.[26,27] An alternate source of high-flow oxygen should be sought if jet ventilation is needed and cannot be supported by the machine's oxygen flush function.

Pneumatic Safety Systems. One of the primary safety goals of contemporary anesthesia machines is to guard against the potential of delivering an excessive concentration of nitrous oxide relative to oxygen (hypoxic mixture). ISO standards require delivery of a nonhypoxic gas mixture to the patient, or generation of an alarm condition.[11] Several safety devices discussed below have been introduced to prevent generating a hypoxic mixture.

OXYGEN SUPPLY FAILURE ALARM SENSOR. Within the oxygen circuit of the intermediate-pressure section of the machine is a sensor that provides an audible and visual warning to the clinician if the oxygen pressure drops below a manufacturer-specified minimum. The alarm is an ISO requirement[11]; under ASTM guidelines, it cannot be silenced until the pressure is restored to the minimum value.[20] The alarm is triggered by a loss of or significant decrease in pipeline pressure, or a nearly empty oxygen tank if the tank was the oxygen source. During normal operation this alarm signal serves as a prompt for the operator to open the oxygen E-cylinder on the machine and troubleshoot the oxygen pipeline source. The minimum threshold pressure for an alarm condition differs among manufacturers and models, because pipeline pressure standards vary significantly throughout the world. The conditions that trigger the alarm should be delineated in the manufacturer's instructions.[11] Numerous types of pneumatic-electrical switches serve as this sensor. Older machines had a purely pneumatic device that gave an audible signal when oxygen pressure dropped (the "Ritchie whistle").[27a] Current machines integrate the output from electronic pressure transducers to create an alarm if pressures drop below predetermined minimums.[21]

OXYGEN SUPPLY FAILURE PROTECTION DEVICES. In addition to generating an alarm condition, oxygen failure influences the flow of other gases within the gas supply system. Sometimes called "fail-safe valves," the oxygen supply failure protection devices are safeguards intended to link the flow of other gases in the gas supply system to the pressure of oxygen. They are an ISO standard.[11] In response to low oxygen pressure within the intermediate-pressure section of the anesthesia machine, the oxygen supply failure protection device either shuts off (binary valve), or reduces (proportional valve) the flow of other gases such as nitrous oxide or air. Unfortunately, the term *fail-safe* as it pertains to these valves is a misnomer and has led to the misconception that they can independently prevent the administration of a hypoxic mixture. If a gas other than oxygen pressurizes the oxygen circuit as a result of hospital pipeline contamination or crossover, the fail-safe valves will remain open. In such a case, only the inspired oxygen concentration monitor and clinical acumen would protect the patient.

Auxiliary Oxygen Flowmeter. Although auxiliary oxygen flowmeters are not mandatory, they are commonly encountered. During normal operation, the auxiliary flowmeter is a convenience feature that allows the use of low-flow oxygen for devices independent of the patient's breathing circuit. Similar to the oxygen flush feature, oxygen flow from the flowmeter is usually accessible even when the machine is not turned on, because the flowmeter is typically fed before the pneumatic power switch in the intermediate-pressure section. As long as oxygen is available from the pipeline inlet or from an attached E-cylinder, the auxiliary oxygen flowmeter can serve as a source of oxygen delivery for use with a manually powered resuscitation bag in the case of a system power failure. The auxiliary oxygen flowmeter may also potentially serve as gas source for a manual jet ventilator; however, not all machines can generate sufficient working pressure.[26,28] Some auxiliary oxygen flowmeters have a DISS connector that would be a better source for manual jet ventilation.[13]

The operator should be aware that the source of oxygen for the auxiliary flowmeter is the same as for the other oxygen flow control valves. This is an important consideration in cases of suspected hospital oxygen pipeline contamination or crossover. If the pipeline oxygen supply line is connected to the machine and the pressure is sufficient, the gas source will be the pipeline even if the auxiliary oxygen tank valve is opened. In a simulation experiment, a nitrous oxide–oxygen pipeline crossover situation was created whereby the inspired oxygen concentration became alarmingly low, and the "patient" became hypoxemic after turning the nitrous oxide flow off. Researchers noted that many study participants tried to make inappropriate use of the auxiliary oxygen flowmeter and oxygen E-cylinders on the machine as an external source of oxygen without disconnecting the pipeline source.[29] The participant's suboptimal management was attributed to a lack of knowledge of the anesthesia machine and its gas supply.

Second-Stage Pressure Regulators. Some machines have second-stage regulators located downstream from the gas supply sources in the intermediate-pressure circuit. These regulators supply constant pressure to the flow control valves and the proportioning system regardless of potential fluctuations in hospital pipeline pressures. They are adjusted to lower pressure levels than the pipeline supply, usually between 14 and 35 psig, depending on the workstation.[30,31,31a]

Low-Pressure Section

The purpose of the high- and intermediate-pressure sections of the anesthesia machine is to deliver a reliable source of breathing gases at a stable and known working pressure to the low-pressure section of the gas supply system. The low-pressure section of the gas supply system begins at the flow control valves and ends at the fresh gas outlet (see Figs. 22.1 and 22.2). The breathing circuit, including the circle system, breathing bag, and ventilator, will be treated separately. Key components include the flow control valves, the flowmeters or flow sensors, the vaporizer manifold, and the anesthetic vaporizers. The low-pressure section is the most vulnerable section to leaks within the gas supply system.

Flow Control Assemblies. The flow control valves on the anesthesia workstation allow the operator to select a *total fresh gas flow* of known composition that enters the low-pressure section of the anesthesia workstation. These valves separate the intermediate-pressure section from the low-pressure section. After leaving the flowmeters, the mixture of gases travels through a common manifold and may be directed through an anesthetic vaporizer if selected. The total fresh gas flow and the anesthetic vapor then travel toward the fresh gas outlet (see Figs. 22.1 and 22.2).[12,19]

ELECTRONIC FLOW SENSORS. Newer anesthesia workstations are increasingly equipped with electronic flow sensors instead of flow tubes. These systems may employ conventional control knobs or an entirely electronic interface to control gas flow. Flows can be displayed numerically or sometimes graphically in the form of a virtual, digitalized flowmeter. Numerous types of flow sensor technologies can be applied, such as hot-wire anemometers, a differential pressure transducer method, or mass flow sensors. An example of an electronic mass flow sensor is seen in Fig. 22.6. The illustrated device relies on the principle of specific heat to measure gas flow.[30] As gas flows through a heated chamber of known volume, a specific amount of electricity is required to maintain the chamber temperature. The amount of energy required to maintain the temperature is proportional to the flow and specific heat of the gas. Regardless of the mechanism of flow measurement, these systems depend on electrical power to provide a display of gas flow. When electrical power is totally interrupted, some backup mechanical means usually exists to control (mechanical flow control) and display (flow tube) oxygen gas flow.

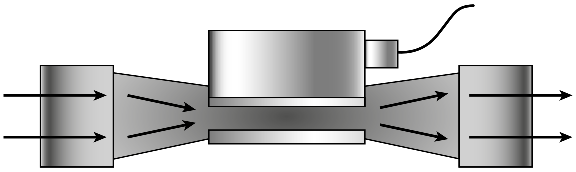

Fig. 22.6 Electronic mass flow sensor. Gas flows past a heated chamber of known volume. The amount of heat (electrical energy) that is required to maintain a set chamber temperature is proportional to the specific heat of the gas and its rate of flow through the chamber. Because the specific heat of the gas is relevant to the calculation, each gas must have its own mass flow sensor. Flow is accurately extrapolated from the energy required to keep the chamber at a constant temperature. (Modified from Yoder M. Gas supply systems. In: *Understanding Modern Anesthesia Systems*. Telford, PA: Dräger Medical; 2009.)

MECHANICAL FLOWMETER ASSEMBLIES. Mechanical flow control and flow display still remain common, even on some newer workstations, either as primary or backup systems.[31a,31b]

FLOW CONTROL VALVES. The flow control valve assembly consists of a flow control knob, a tapered needle valve, a valve seat, and a pair of valve stops (Fig. 22.7).[12] The inlet pressure to the assembly is determined by the pressure characteristics of the machine's intermediate-pressure segment. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Because their use is frequent and the consequences of damage are significant, the controls must be constructed so extremes of rotation will not cause disassembly or disengagement.

Contemporary flow control valve assemblies have numerous safety features. The oxygen flow control knob is physically distinguishable from the other gas knobs. It is distinctively fluted, may project beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases.[11] All knobs are color coded for the appropriate gas, and the chemical formula or name of the gas must be permanently marked on each knob. Flow control knobs are recessed or protected with a shield or barrier to minimize inadvertent change from a preset position. If a single gas has two flow tubes, the tubes are arranged in series and are controlled by a single flow control valve.[20]

FLOW TUBES. With a traditional flowmeter assembly, the flow control valve regulates the amount of flow that enters a tapered, transparent flow tube known as a *variable orifice flowmeter* or *Thorpe tube*. These glass tubes are narrowest at the bottom and widen at the top. A mobile indicator float inside the calibrated flow tube indicates the amount of flow passing through the associated flow control valve. The quantity of flow is indicated on a scale specific to the

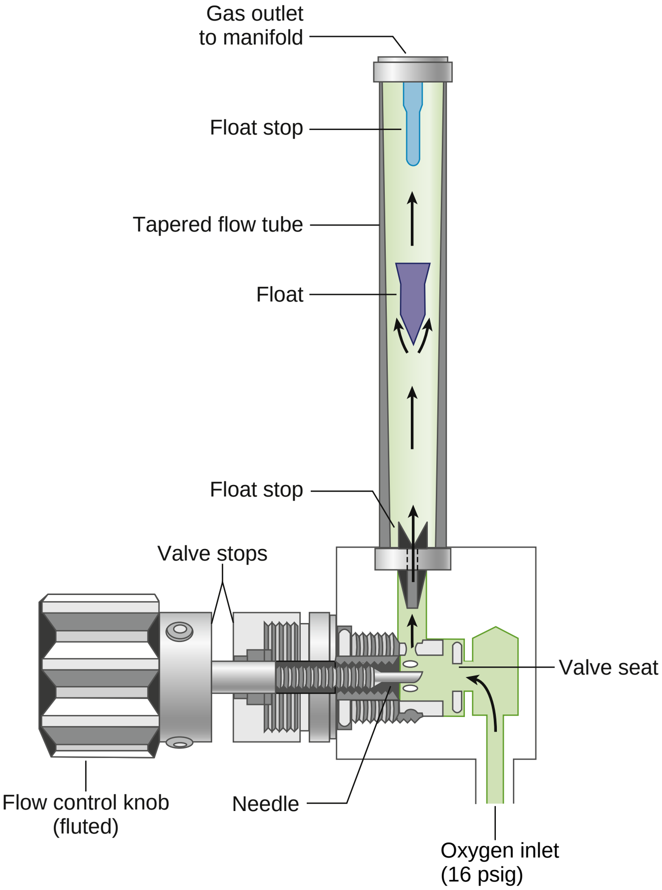

Fig. 22.7 Oxygen flowmeter assembly. The oxygen flowmeter assembly is composed of the flow control valve assembly and the flowmeter subassembly. (From Bowie E, Huffman LM. *The Anesthesia Machine: Essentials for Understanding.* Madison, WI: Ohmeda, BOC Group; 1985.)

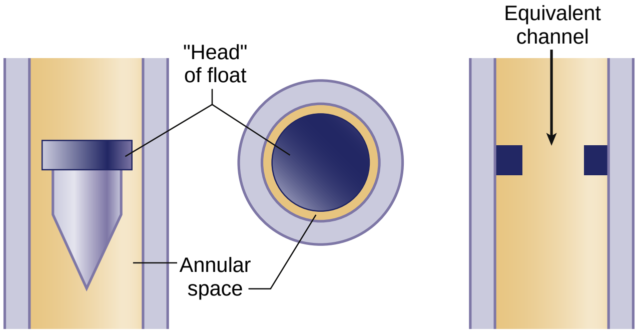

Fig. 22.8 The annular space. The clearance between the head of the float and the flow tube is known as the annular space. It can be considered equivalent to a circular channel of the same cross-sectional area. (Redrawn from Macintosh R, Mushin WW, Epstein HG, eds. *Physics for the Anaesthetist.* 3rd ed. Oxford: Blackwell Scientific; 1963.)

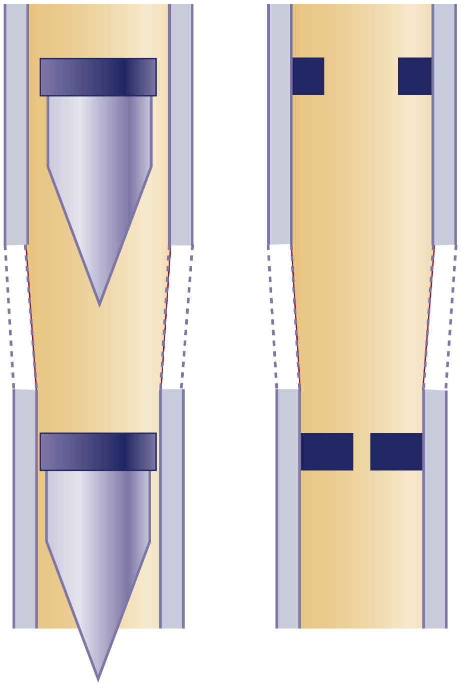

Fig. 22.9 Flow tube constriction. The *lower pair* of illustrations represents the lower portion of a flow tube. The clearance between the head of the float and the flow tube is narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining the gas flow rate through this tubular constriction. The *upper pair* of illustrations represents the upper portion of a flow tube. The equivalent channel is orificial because its length is less than its diameter. Density is dominant in determining the gas flow rate through this orificial constriction. (Redrawn from Macintosh R, Mushin WW, Epstein HG, eds. *Physics for the Anaesthetist.* 3rd ed. Oxford: Blackwell Scientific; 1963.)

flow tube.[12,19] Opening the flow control valve allows gas to travel through the space between the float and the flow tube. This space is known as the *annular space*, and it varies in size depending on the position in the tube (Fig. 22.8). The indicator float hovers freely in an equilibrium position in the tube where the upward force resulting from gas flow equals the downward gravity force on the float at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flowmeters are commonly referred to as *constant-pressure* flowmeters because the decrease in pressure across the float remains constant for all positions in the tube.[12,32,33]

Flow through the annular space can be laminar or turbulent, depending on the gas flow rate (Fig. 22.9). The characteristics of a gas that influence its flow rate through a given constriction are viscosity (laminar flow) and density (turbulent flow). Because the annular space behaves as a tube at low flow rates, laminar flow is present, and *viscosity* determines the gas flow rate. At high flow rates, the annular space behaves like an orifice. Turbulent gas flow is present and gas *density* predominantly influences the flow. Because the viscosity and density of the gas affect flow through annular space around the float, the calibrated flow tubes are gas specific. The tube, the float, and the scale are inseparable. Although temperature and barometric pressure can influence gas density and viscosity, under normal clinical circumstances, flow tube accuracy is not significantly affected by mild changes in temperature or pressure.

The float or bobbin within the flow tube is usually constructed so that it rotates to indicate that gas is flowing and that the indicator is not stuck in the tube. A stop at the top of the flowmeter tube prevents the float from occluding the outlet. Two flowmeter tubes are sometimes placed in series, with a fine flow tube displaying low flows and a coarse flow tube indicating higher flows.

Problems With Flowmeters. Flow measurement error can occur even when flowmeters are assembled properly. Dirt or static electricity can cause a float to stick and misrepresent actual flow. Sticking of the indicator float is more common in the low-flow ranges because the annular space is smaller. A damaged float can cause inaccurate readings because the precise relationship between the float and the flow tube is altered. Backpressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flowmeters are not aligned properly in the vertical position (plumb), readings can be inaccurate because tilting distorts the annular space.[12,34,35]

The flow tube has historically been a very fragile component of the anesthesia workstation. Subtle cracks and chips may be overlooked and can cause errors in delivered flow.[34] Leaks can also occur at the O-ring junctions between the glass flow tubes and the metal manifold. Flow tube leaks are a potential hazard because the flowmeters are located downstream from all hypoxemia safety devices, except the breathing circuit oxygen analyzer.[33,36,37] Fig. 22.10 shows an example where an unused air flow tube develops a large leak. When the nitrous oxide flowmeter is in the downstream position (Fig. 22.10*A* and *B*), a hypoxic mixture can occur because a substantial portion of the oxygen flow passes through the leak in the air flow tube, and mainly nitrous oxide is directed to the common gas outlet. Safer configurations are shown in Fig. 22.10*C* and *D*, in which the oxygen flowmeter is located in the downstream position. A portion of the nitrous oxide flow escapes through the leak, and the remainder goes toward the common gas outlet. A hypoxic mixture is less likely because all the oxygen flow is advanced by the nitrous oxide (this principle is known as the Eger flow sequence). It has been an industry standard that oxygen be delivered downstream of all other gases,[20] although current ISO standards require only that oxygen be at either end of a bank of flowmeters.[11] It is important to remember that in the case of a leak in the oxygen flow tube, a hypoxic mixture may result even when oxygen is located in the downstream position.[34]

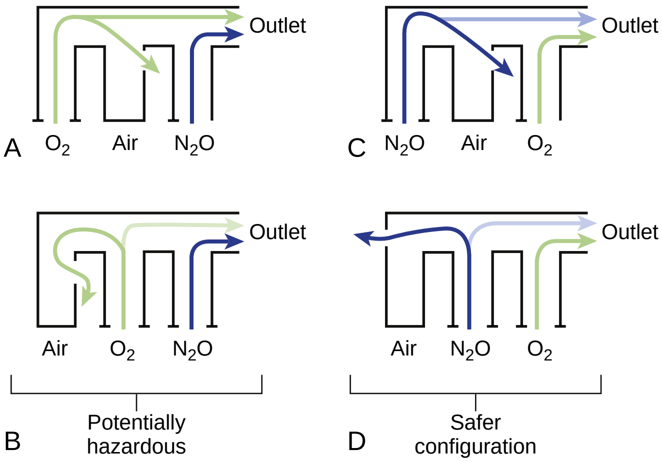

Fig. 22.10 The flowmeter sequence is a potential cause of hypoxia. In the event of a flowmeter leak, a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (A and B). A safer configuration exists when oxygen is located in the downstream position (C and D). See text for details. (Modified from Eger EI II, Hylton RR, Irwin RH, et al. Anesthetic flowmeter sequence: a cause for hypoxia. *Anesthesiology.* 1963;24:396.)

PROPORTIONING SYSTEMS. Anesthesia workstations are equipped with an oxygen failure protection device in the intermediate-pressure section that, in response to reduced oxygen pressure, either proportionally reduces or completely inhibits nitrous oxide. However, this system does not prevent the user from selecting a hypoxic gas mixture for delivery to the fresh gas outlet. On anesthesia workstations with electronically controlled gas flow, the machine is programmed to prevent the user from selecting a hypoxic gas mixture for delivery to the fresh gas outlet. For mechanically controlled flowmeters, the concern is that a user could mistakenly select oxygen and nitrous oxide flows that would result in a hypoxic mixture. According to the ISO, an alarm condition is insufficient and the machine must have a system to prevent delivery of a hypoxic mixture.[11] This is accomplished by a pneumatic-mechanical interface between the oxygen and nitrous oxide flows or by mechanically linking the oxygen and nitrous oxide flow control valves. This way, no matter how high the operator attempts to turn up the nitrous oxide, or how low the operator tries to turn down the oxygen flow, when nitrous oxide is running, the machine will automatically adjust the ratio of these flows so that a hypoxemic gas mixture cannot be delivered. The specific devices used to accomplish this control vary among manufacturers. Two examples are briefly discussed here.

The North American Dräger sensitive oxygen ratio controller system (SORC) is a pneumatic-mechanical, oxygen–nitrous oxide interlock system designed to maintain a ratio of no less than 25% oxygen to 75% nitrous oxide flow into the breathing circuit by limiting the nitrous oxide flow when necessary.[21] The SORC, located after the flow control valves, consists of an oxygen chamber with a diaphragm, a nitrous oxide chamber with a diaphragm, and a nitrous oxide proportioning valve (Fig. 22.11). All are interconnected by a mobile horizontal shaft. As oxygen flows out of the SORC, it encounters a resistor that creates backpressure in the oxygen chamber, which causes the diaphragm to move to the right, thereby opening the nitrous oxide proportioning valve. As the oxygen flow is increased, so too is the backpressure and the rightward motion of the shaft. If the nitrous oxide flow is now turned on, it will also flow into the SORC, through the proportioning valve, and past its resistor to create backpressure that will press on the diaphragm in its respective chamber. The counterbalance between the two gas flows (backpressures) determines the positioning of the nitrous oxide proportioning valve.[21] If the oxygen is turned down too low (<1/3 of the nitrous oxide flow), the shaft will move to the left and thus limit the nitrous oxide flow. If the operator tries to turn up the nitrous oxide too high relative to the oxygen flow, the SORC will limit the nitrous oxide flow because of the nitrous oxide backpressure and leftward movement of the valve. If the oxygen flow is decreased to less than 200 mL/min, the proportioning valve will close completely.[38]

A mechanical proportioning system that remains in use today on many anesthesia machines is the GE/Datex-Ohmeda Link-25 system. The system provides mechanical integration of the nitrous oxide and oxygen flow control valves to maintain a minimum oxygen concentration with a maximum nitrous oxide:oxygen flow ratio of 3:1. Independent adjustment of either valve is allowed as long as the minimum threshold is met. The Link-25 automatically increases oxygen flow when the nitrous oxide flow is increased above the 3:1 ratio. It also will lower nitrous oxide flow if oxygen flow is decreased below that ratio. Fig. 22.12 shows the Link-25 system. A 15-tooth sprocket is attached to the nitrous oxide flow control valve, a 29-tooth sprocket is attached to the oxygen flow control valve and a chain physically links the sprockets. When the nitrous oxide flow control valve is turned through two revolutions, the oxygen flow control valve will revolve once because of the 2:1 gear ratio. The final 3:1 flow ratio results because the flow control valve needle for nitrous oxide has a faster taper than does the oxygen valve needle. The Link-25 system uses a stop tab on each valve stem to allow for independent adjustment of oxygen or nitrous oxide as long as the mixture is at least 25% oxygen; attempting to turn the valve controller past that point will engage the chain and effect a change in the other gas. In addition, the system is designed so that nitrous oxide cannot flow unless the oxygen flow is at least 200 mL/min.[38a]

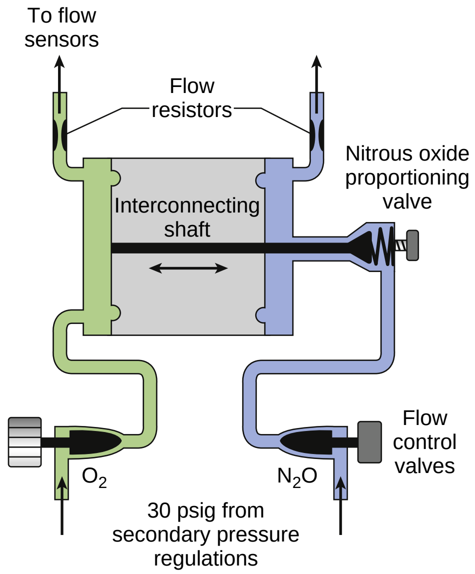

Fig. 22.11 North American Dräger sensitive oxygen ratio controller system (SORC) (Dräger Medical, Telford, PA). The SORC is a pneumatic-mechanical interlock system designed to maintain a ratio of no less than 25% oxygen/75% nitrous oxide regardless of operator input. Differential oxygen and nitrous oxide flows and the resultant chamber backpressures determine the position of the nitrous oxide proportioning valve. The SORC requires a minimum oxygen flow of 200 mL/min for the nitrous oxide proportioning valve to open. See text for details. (Modified from Yoder M. Gas supply systems. In: *Understanding Modern Anesthesia Systems*. Telford, PA: Dräger Medical; 2009.)

Although both proportioning systems are designed to prevent delivery of a hypoxic gas mixture to the common gas outlet, their effect on the output may be different. If the operator turns down oxygen flow below 25% oxygen, both the Link-25 and SORC systems will respond by decreasing the flow of nitrous oxide. If the operator subsequently increases the set oxygen flow, the nitrous oxide flow will remain at the new, lower value with the Link-25 system, because the mechanical linkage will have physically changed the nitrous oxide control valve setting. With the SORC system, on the other hand, the nitrous oxide flow will return to the higher, previously set value when adequate oxygen flow is restored. If the operator increases nitrous oxide flow beyond the set safe range, the Link-25 system will increase the oxygen flow by changing the setting on the oxygen control valve. The SORC system will instead prevent the increase in nitrous oxide flow from occurring. If the operator subsequently reduces the nitrous oxide flow setting, the oxygen flow will remain at the new, higher level with the Link-25, and will remain unchanged with the SORC.

PROPORTIONING SYSTEM MALFUNCTION. Proportioning systems are not immune from failure, and workstations equipped with proportioning systems can still deliver a hypoxic mixture under certain conditions. Many case reports have described proportioning system malfunction.[39-43] Other situations that may defeat the purpose of the proportioning system require operator vigilance. Both mechanical and pneumatic proportioning systems can be defeated if a gas other than oxygen is present in the oxygen pipeline. Proportioning systems such as the Link-25 function at the level of the flow control valves. A leak downstream from these devices, such as a broken

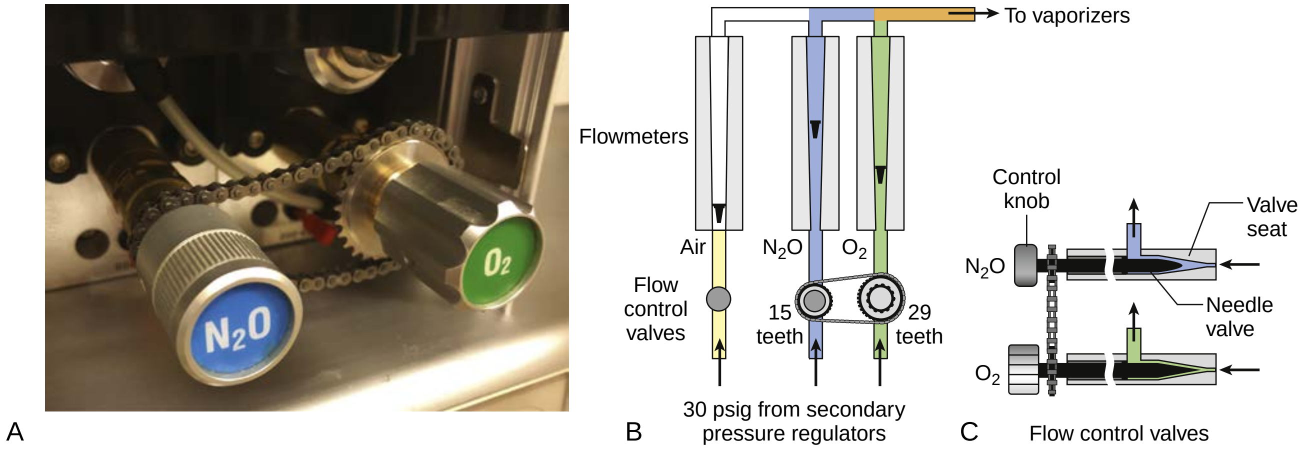

Fig. 22.12 GE/Datex-Ohmeda Link-25 nitrous oxide: oxygen proportioning system. The system prevents the operator from selecting more than a 75% nitrous oxide–25% oxygen (3:1) mixture by two separate but interdependent means. (A) Link-25 proportioning system on a GE Healthcare Aestiva anesthesia workstation with front panel removed. (B) Mechanical linkage of the control valves maintains no more than a 2:1 ratio. (C) A faster taper of the nitrous oxide valve needle allows more gas flow through the valve per turn relative to flow through the oxygen valve per turn, thus resulting in the maximal 3:1 ratio. A stable and equal pressure supply to the valves is provided by the secondary pressure regulator for oxygen and a balance regulator for nitrous oxide. See text for additional details. (Datex-Ohmeda: Aestiva anesthesia machine: technical reference manual, Madison, Wis: Datex-Ohmeda 2006.)

oxygen flow tube, could result in delivery of a hypoxic mixture to the common gas outlet. In this situation, oxygen escapes through the leak, and the predominant gas delivered is nitrous oxide. Finally, volatile inhaled anesthetic agents are added to the mixed gases downstream from both the flowmeters and the proportioning system. Concentrations of less potent inhaled anesthetic agents such as desflurane may account for a larger percentage of the total fresh gas composition than is the case with more potent agents. Because significant percentages of these inhaled anesthetic agents may be added downstream of the proportioning system, the resulting gas-vapor mixture may contain an inspired oxygen concentration less than 21% despite a functional proportioning system. The additional complexity of the circle system (discussed below) means that the oxygen concentration of the fresh gas flow delivered to the breathing circuit may be very different from the patient's actual fraction of inspired oxygen (FiO_2). In each case, the presence of a functioning oxygen analyzer in the patient's breathing circuit is the last protection against a hypoxic gas mixture.

Vaporizer Mount and Interlock System

VAPORIZER MOUNTING SYSTEMS. Removable modern vaporizer mounts allow for rapid replacement or exchange of anesthetic vaporizers. This allows for ease of maintenance, fewer required vaporizer positions on the workstation, and the ability to remove the vaporizer if malignant hyperthermia is suspected.[44] Detachable mounting systems can lead to problems such as low-pressure systems leaks or fresh gas flow obstruction as a result connection-related failures.[44-49] After adding or changing a vaporizer on the anesthesia machine, the operator should make sure it is seated properly and cannot be dislodged once locked. The operator should then perform a vaporizer leak test, if required by the manufacturer.

VAPORIZER INTERLOCK DEVICES. All anesthesia workstations must prevent fresh gas from flowing through more than one vaporizer at time.[11] The design of vaporizer interlock devices varies significantly. Operators should be aware that these devices are not immune from failure, and anesthetic overdose can be a potential consequence.[50-53]

Outlet Check Valve. Many older Datex-Ohmeda anesthesia machines and a few contemporary workstations (e.g., GE/Datex-Ohmeda Aestiva and Aespire) have a one-way check valve located between the vaporizer and the common gas outlet in the mixed-gas pipeline (see Fig. 22.1). The purpose of this valve is to prevent backflow into the vaporizer during positive-pressure ventilation, thereby minimizing the effects of intermittent fluctuations in downstream pressure on the concentration of inhaled anesthetics (see the discussion of intermittent backpressure in the section on anesthetic vaporizers). The presence or absence of this check valve historically influenced which *manual* leak test of the low-pressure system was indicated because it precluded positive-pressure tests to detect for leaks upstream of the valve (see the section on checking your anesthesia workstation).

ANESTHETIC VAPORIZERS

In 1846, William T. G. Morton performed the first public demonstration of ether anesthesia using an ingenious, yet simple inhaler (Fig. 22.13).[54-56] Although the device was effective in delivering anesthetic vapor, Morton's ether inhaler had no means of regulating output concentration or compensating for temperature changes caused by vaporization of the liquid anesthetic and the ambient environment. These two issues were central to the subsequent development and evolution of modern anesthetic vaporizers. Modern variable bypass–type vaporizers are temperature compensated and can maintain desired outputs accurately over a wide range of input gas flow rates. In 1993, with the introduction of desflurane to the clinical setting, an even more sophisticated vaporizer was introduced to handle the unique physical properties of this agent. Vaporizers blending both old technology and computer control have emerged as "cassette" vaporizer systems. An injection-type vaporizer has also been reintroduced. This vaporizer injects precise amounts of liquid anesthetic agent into the fresh gas stream. Before discussing these systems in detail, a brief review of physical/chemical principles is necessary to understand the operation, construction, and design of contemporary anesthetic vaporizers.

Physics

The Ideal Gas Law. When sealed in a container, gas molecules collide with the walls and exert a force or pressure. This pressure is directly proportional to the number of molecules or moles *(n)* of gas present within the container and to the temperature *(T)* in degrees kelvin, and inversely proportional to the volume *(V)* that confines the gas. (One mole of a substance is equal to 6.022×10^{23} [Avogadro's number] molecules of that substance.) The ideal gas law is:

$$PV = nRT$$

R (the universal gas constant) = 8.314 L kPa/mol *K or 62.364 L mm Hg/mol*K

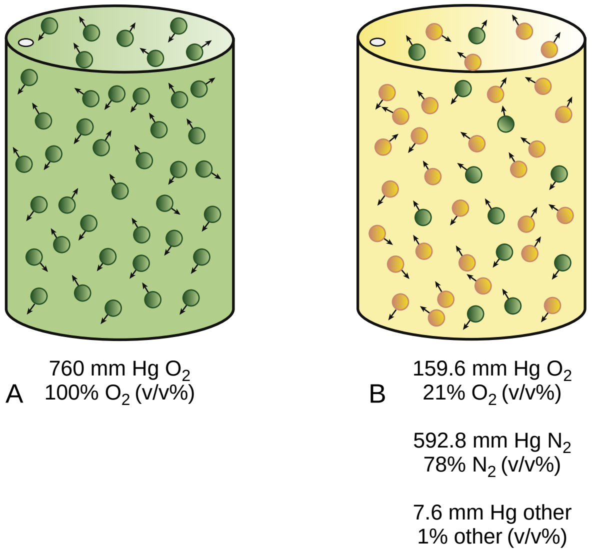

Fig. 22.14 Partial pressures. (A) Theoretical container filled with 100% oxygen at 1 atm pressure (760 mm Hg). The oxygen molecules account for the entirety of the pressure. $P_{total} = P_{oxygen} = 760$ mm Hg. (B) Pure oxygen is replaced with air, and now the nitrogen, oxygen, and other rare gases each contribute to the total pressure in proportion to their volume percent (v/v%). $P_{total} = P_{oxygen} + P_{nitrogen} + P_{other} = 760$ mm.

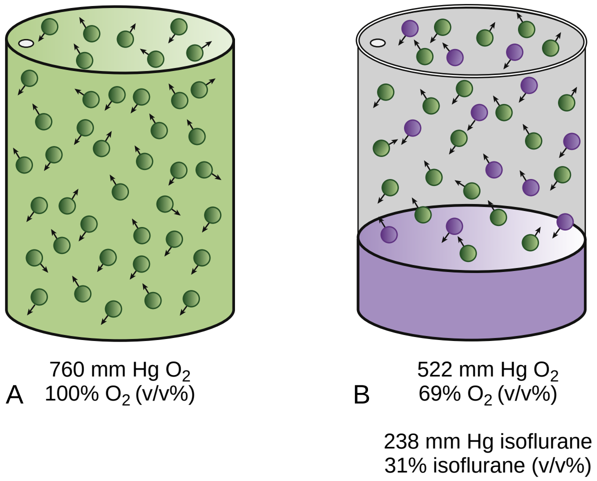

Fig. 22.15 Evaporation (vaporization) and vapor pressure. (A) Theoretical container with 100% oxygen. $P_{total} = P_{oxygen} = 760$ mm Hg, see Fig. 22.14. (B) Isoflurane is added to the container, and the temperature is maintained at 20°C (68°F). Evaporation commences, and isoflurane molecules begin to displace oxygen molecules out of the container. When the rate of vaporization is equal to the rate of condensation, the gas above the liquid is said to be "saturated" with isoflurane. The partial pressure of the isoflurane at this point is called the saturated vapor pressure (SVP), which at this temperature equals 238 mm Hg. $P_{total} = P_{oxygen} + P_{isoflurane} = 760$ mm.

The ideal gas law provides an important framework for understanding the behavior of anesthetic gases within vaporizers, anesthesia delivery equipment, and the pulmonary alveolus. Key assumptions of this law are that gas molecules (1) behave as points in space and (2) undergo perfectly elastic collisions without attracting or repelling one another or the walls of the container. These assumptions are valid for dilute anesthetic gases at normal operating conditions.

Dalton's Law of Partial Pressures. When a mixture of ideal gases exists in a container, each gas creates its own pressure, which is the same pressure as if the individual gas occupied the container alone. The total pressure may be calculated by simply adding together the pressures of each gas. This is known as Dalton's law of partial pressures, where the individual pressures (P_i) exerted by each of the constituent gases are referred to as *partial pressures*:[57,58]

$$P_{total} = P_1 + P_2 + P_3 + \ \ldots$$

Another useful expression, which can be derived by combining Dalton's law with the ideal gas law, is:

$$P_A = (n_A/n_{total})\,P_{total} = (v/v\%)\,P_{total}$$

which states that the partial pressure of gas A can be calculated by multiplying the total pressure of the mixture by the mole fraction (n_A/n_{total}), or the volume percent ($v/v\%$), of gas A. The volume percent tends to be more useful in day-to-day anesthesia practice (see below).

As a first step to understanding vaporizer function, it is useful to look at an example of Dalton's law of partial pressures. In Fig. 22.14*A*, pure oxygen fills a theoretical container that is open to the environment through a very small hole. The pressure in the container is equal to the ambient pressure, which at sea level is 760 mm Hg or 1 atm or 101.325 kPa, and generated entirely by the oxygen molecules. In Fig. 22.14*B*, the container is filled with air, and the total pressure is generated by the additive partial pressures of oxygen, nitrogen, and trace amounts of rare gases.

Evaporation and Vapor Pressure. Volatile liquids, such as inhaled anesthetic agents, are characterized by a high propensity to enter the gas phase, or *vaporize*. When a volatile liquid is exposed to air or other gases, molecules at the liquid surface with sufficient kinetic energy escape and enter the vapor phase. This process is known as *evaporation*, which is purely a surface phenomenon (in contrast to *boiling*, which occurs throughout the liquid). If liquid volatile anesthetic is placed within a contained space, such as a vaporizer, molecules will escape into the vapor phase until the rate of evaporation equals the rate of return to the liquid phase (a process known as *condensation*). When this equilibrium is reached, the gas above the liquid is said to be "saturated" with anesthetic (Fig. 22.15). The anesthetic molecules in the gas phase create a partial pressure known as the *saturated vapor pressure*, or simply *vapor pressure*. Liquids with a greater tendency to evaporate and generate higher vapor pressures are described as "more volatile."

Vapor pressure is an unique physical property of a substance at any given temperature (Fig. 22.16). Vapor pressure is *not* affected by changes in atmospheric pressure.[59] As illustrated in Fig. 22.17 for the isoflurane, evaporation is diminished at colder temperatures because fewer molecules possess sufficient kinetic energy to escape into the vapor phase. Conversely, at warmer temperatures, evaporation is enhanced and vapor pressure increases. Although

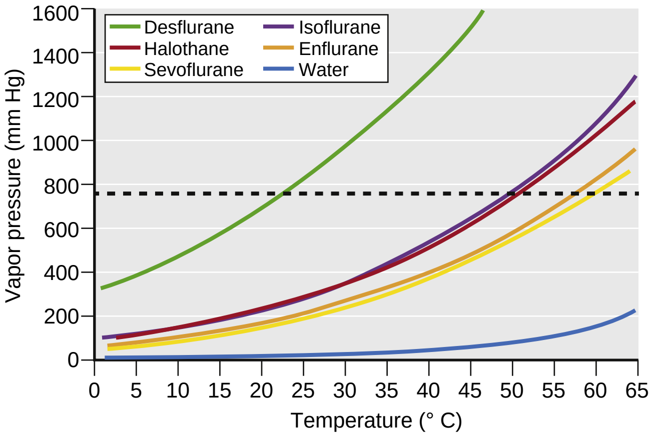

Fig. 22.16 Vapor pressure-versus-temperature curves for desflurane, isoflurane, halothane, enflurane, sevoflurane, and water. Note that the curve for desflurane differs dramatically from that of the other inhaled anesthetic agents. Also note that all inhaled agents are more volatile than water. Dashed line indicates 1 atm (760 mm Hg) of pressure, which illustrates the boiling point at sea level (normal boiling point). (From inhaled anesthetic package insert equations and Susay SR, Smith MA, Lockwood GG. The saturated vapor pressure of desflurane at various temperatures. *Anesth Analg*. 1996;83:864–866.)

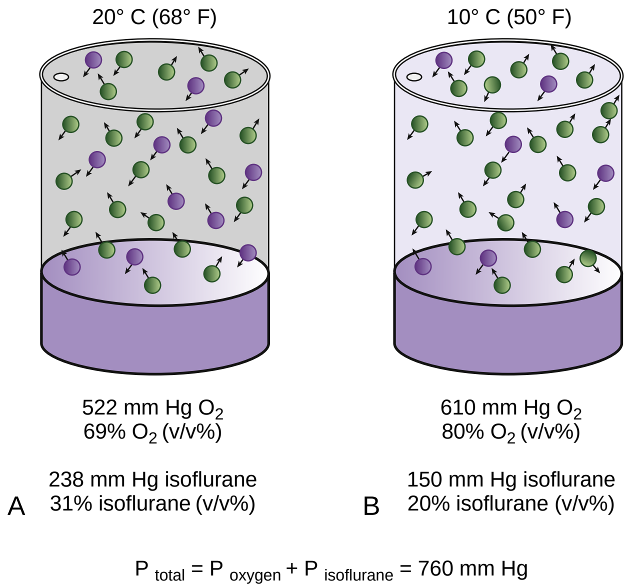

Fig. 22.17 The impact of temperature on vapor pressure. (A) Chamber containing oxygen and isoflurane at its saturated vapor pressure (SVP) at 20°C (68°F). At evaporative equilibrium, the SVP of isoflurane in the container represents 31% of the entire gas composition by volume (*v/v*%). (B) Decreasing the temperature to 10°C (50°F) substantially lowers the isoflurane vapor pressure to 150 mm Hg and causes isoflurane to represent only 20% of the entire gas volume (*v/v*%). This example assumes that some oxygen can enter the container through a tiny hole to replace the condensed isoflurane molecules.

operating room (ambient) temperature can raise or lower liquid anesthetic vapor pressure, the cooling influence of evaporation (the latent heat of vaporization, *see below*) has a far more pronounced and dynamic effect. The impact of evaporative temperature change on vaporizer and anesthetic inhaler output has been recognized since the mid-1800s, and addressing this phenomenon has been one of the principal factors influencing design of anesthetic vaporizers.

Because vapor pressures are unique to each liquid anesthetic agent, vaporizers must be constructed in an agent-specific manner. If a vaporizer is inadvertently filled with the incorrect liquid anesthetic agent, the vaporizer output will change (see the discussion of misfilling in the section on variable bypass vaporizers).[60,61]

Expressing Gas Concentrations and Minimum Alveolar Concentration. When describing a mixture of gases, we can quantify the proportion of an individual gas by either its *partial pressure* (mm Hg), or by the percentage of volume occupied by the gas relative to the sum of all gases present, which is known as *volume percent* or *volume-volume percent* (*v*/*v*%)[62]:

$$\text{Volume percent}(v/v\%) = (\text{volume of gas } x/\text{total gas volume}) * 100\%$$

The volume that an ideal gas occupies at a given temperature and pressure is related to the number of molecules of gas present, but not the size or identity of the molecules. This statement is known as the *Avogadro Hypothesis*. Using the ideal gas law, it is easy to calculate that at 1 atm (760 mm Hg) of pressure and 20°C (68°F or 293°K), conditions that might be found in a typical operating room, 1 mole of an ideal gas occupies a volume of about 24 L. The same is true for any mixture of ideal gases containing a total of 1 mole of gas molecules. Therefore, because partial pressure is directly proportional to the number of molecules of a gas present in the mixture, we can also use partial pressures to calculate the volume percent of any constituent gas[63]:

$$\begin{aligned}\text{Volume percent } (v/v\,\%) &= \\ &(\text{partial pressure of gas } x/\text{total pressure}) * 100\% \\ &= (P_x/P_{\text{total}}) * 100\%\end{aligned}$$

Using air at sea level ($P_{\text{total}} = P_{\text{atm}} = 760$ mm Hg) as an example:

Knowing the partial pressures of the constituent gases of air…

$$P_{\text{atm}} = P_{\text{oxygen}} + P_{\text{nitrogen}} + P_{\text{other}}$$

$$P_{\text{atm}} = 760\text{ mm Hg} \approx (160\text{ mm Hg oxygen}) + (592\text{ mm Hg nitrogen}) + (8\text{ mm Hg other gases})$$

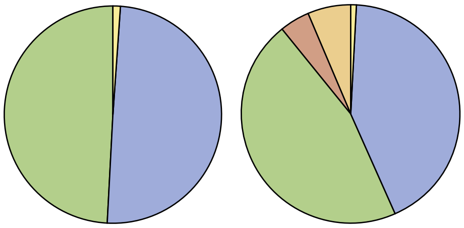
… we can then calculate the volume percent (*v*/*v*%) of oxygen…

$$\text{Oxygen } (v/v\%) \sim P_{\text{oxygen}}/P_{\text{amt}} \sim 160\text{ mm Hg}/760\text{ mm Hg} \sim 21\%$$

When anesthesiologists describe inhaled and exhaled anesthetic concentrations, they typically use volume percent. One percent isoflurane is equal to 7.6 mm Hg isoflurane at sea level. The amount of oxygen and nitrous oxide in the breathing gas is also typically described in terms of volume percent. However, CO_2 content (i.e., end-tidal carbon dioxide [ETCO_2]) is usually displayed as a partial pressure (mm Hg). This was probably adopted because of the relatively close correlation between ETCO_2 and arterial partial pressure of carbon dioxide (PaCO_2), and the latter's common expression as a partial pressure. Fig. 22.18 illustrates a typical composition of the breathing gases during anesthesia in terms of concentration (*v*/*v*%) and partial pressures.

The minimum alveolar concentration (MAC) is described in terms of volume percent. MAC is the concentration of anesthetic that prevents movement from surgical stimulus in 50% of individuals.[64] MAC is an age-dependent phenomenon,[65] and it can also be affected by other variables. MAC is a clinically useful value given that vaporizer control knobs are marked and calibrated in terms of anesthetic concentration. However, it is actually the anesthetic partial pressure (mm Hg) value in the brain that is responsible for anesthetic depth. The corresponding partial pressure for each MAC value is known as the minimal alveolar partial pressure (MAPP), as listed in Table 22.1.[66] When discussing anesthetic vaporizers, it is useful to think about their output in terms of partial pressure and how it relates to volume percent and MAC, especially when considering changes in ambient pressure.

Latent Heat of Vaporization. When a liquid such as a volatile anesthetic evaporates into the gas phase, energy is required to overcome the attractive intermolecular forces between molecules in the liquid phase (a property known as *cohesion*). The needed energy is absorbed from the surroundings in the form of *heat*, and is the reason why the human body is cooled by the evaporation of sweat. The amount of energy absorbed by a specific liquid during evaporation is referred to as the *latent heat of vaporization*. It is more precisely defined as the amount of energy in joules or calories (1 calorie = 4.184 joules) required to change 1 g of liquid into vapor at a constant temperature. In a well-insulated container, the energy for vaporization must come from the liquid itself. In the absence of an outside heat source, the remaining liquid cools as vaporization progresses. This leads to significant reductions in vapor pressure (see Fig. 22.16) and therefore the number of volatile anesthetic molecules in the gas phase (see Fig. 22.17).[44,59,67] If vaporizer design does not mitigate and compensate for evaporative cooling, output will decrease.



Gas	Inhalation		Exhalation	
	mm Hg	v/v%	mm Hg	v/v%
Sevoflurane	9	1.2	8	1.1
Oxygen	378	50	323	42
N_2O	373	49	347	46
CO_2	–	–	35	4.5
H_2O	–	–	47*	6.2
Total	760	100	760	100

*Saturated vapor pressure of water at body temperature.

Fig. 22.18 Common units of measure for breathing circuit gases: typical values for an oxygen-nitrous oxide-sevoflurane anesthetic. Anesthetic agent, oxygen, and nitrous oxide concentrations are typically expressed in volume percent (*v/v%*). Carbon dioxide is commonly described as a partial pressure (mm Hg).

Boiling Point. The *boiling point* of a liquid is defined as the temperature at which vapor pressure equals atmospheric pressure and the liquid begins to undergo rapid vaporization.[44,67] From the definition above, it is important to note that the boiling point changes depending on atmospheric pressure. Whereas evaporation is a surface phenomenon, boiling is a bulk phenomenon that occurs throughout the interior of the liquid. The boiling point of a liquid is inversely related to volatility. For example, water is not particularly volatile (see Fig. 22.16) and its boiling point of 100°C (212°F) at sea level is much higher than all of the inhaled anesthetic agents. Table 22.1 lists the *normal boiling point* (defined as the boiling point at a pressure of 1 atm) of the common volatile anesthetic agents. While most inhaled anesthetics boil in the range of 48° to 59°C (118°-138°F), desflurane has a normal boiling point close to room temperature (22.8°C or 73°F).

The boiling point of contemporary volatile anesthetic agents is not relevant to vaporizer design under most clinical situations. Desflurane, however, has a high saturated vapor pressure and boils at a temperature commonly encountered in clinical settings. These properties mandate a special vaporizer design to control agent delivery (see section on desflurane vaporizer). Isoflurane and halothane could theoretically boil at high altitudes and very high

TABLE 22.1 Physical Properties of Inhaled Volatile Anesthetic Agents

Property	Halothane	Isoflurane	Sevoflurane	Desflurane
SVP[*] @ 20°C (mm Hg)	243	238	157	669
SVC[†] @ 20°C at 1 atm[‡] (*v/v%*)	32	31	21	88
MAC[§] at age 40 year (*v/v%*)	0.75	1.2	1.9	6.0
MAPP[¶] (mm Hg)	5.7	9.1	14.4	45.6
Boiling point @1 atm (°C)	50.2 (122.4°F)	48.5 (119.3°F)	58.6 (137.3°F)	22.8 (73°F)

[*] *SVP*, Saturated vapor pressure. From anesthetic prescribing information.

[†] *SVC*, Saturated vapor concentration: the percentage of anesthetic agent relative to ambient pressure within an equilibrated (saturated) container (SVP/ambient pressure).

[‡] *1 atm*, 1 atmosphere = ambient pressure at sea level (760 mm Hg).

[§] *MAC*, Minimum alveolar concentration: the alveolar concentration that produces immobility in response to a noxious stimulus in 50% of subjects.[64] The denominator is approximately sea level pressure (760 mm Hg).

[¶] *MAPP*, Minimum alveolar partial pressure. The alveolar partial pressure that produces immobility in response to a noxious stimulus in 50% of subjects (the numerator in the MAC calculation).[66] Not affected by altitude. Calculated as MAC (fraction) × 760 mm Hg (i.e., for isoflurane = 0.012 × 760 mm Hg).

v/v%, Volume percent.

temperatures. At least one vaporizer manufacturer specifies a maximum safe operating temperature for these anesthetic agents.[68]

Specific Heat. The *specific heat* is the amount of energy required to increase the temperature of 1 g of a substance by 1°C.[44,67] Water, for example, has a specific heat of exactly 1 calorie g^{-1} deg^{-1}. The concept of specific heat is important to the design, operation, and construction of vaporizers in two ways. First, the specific heat of a liquid anesthetic determines how much heat must be supplied to maintain a constant temperature due to the latent heat of vaporization. Second, vaporizers are built from materials with a high specific heat in order to better resist temperature changes associated with evaporative cooling.

Thermal Conductivity. Thermal conductivity is a property that describes how well heat flows through a substance. The higher the thermal conductivity, the better a substance conducts heat.[44] Vaporizers are constructed of metals with relatively high thermal conductivity, which helps maintain a uniform internal temperature during evaporation by allowing efficient heat absorption from the environment. By contrast, coffee mugs should be made of materials with a low thermal conductivity to slow heat loss to the environment.

Modern Vaporizer Types

Vaporizer nomenclature can be somewhat confusing, especially if the historical context of vaporizer, workstation, and breathing circuit evolution is not considered (Table 22.2). Vaporizers are first designated as *in-circuit* or *out-of-circuit*, which describes their relationship to the patient's breathing circuit. Virtually all modern vaporizers are out-of-circuit, and their controlled output is introduced into the breathing circuit through a fresh gas line. In-circuit vaporizers are found mainly within the so-called *draw-over* anesthesia systems, which are of great historical significance in anesthesiology.

The second designation involves the specific types of vaporizers, and these currently include the variable bypass vaporizer (e.g., GE/Datex-Ohmeda Tec 7), the dual-circuit vaporizer (e.g., the classic GE/Datex-Ohmeda Tec 6 desflurane vaporizer), the cassette vaporizer (e.g., GE/Datex-Ohmeda Aladin cassette), the injection vaporizer (e.g., the Maquet vaporizer), and the now historical measured-flow vaporizer (e.g., Copper Kettle). Variable bypass vaporizers can be subcategorized as plenum type, which are out-of-circuit and have relatively high internal flow resistance (the term "plenum" refers to a chamber where gas flows under positive pressure), or draw-over type, which are in-circuit and have low internal resistance. Most modern variable bypass vaporizers are plenum type and are located out-of-circuit, like those seen in Figs. 22.1 and 22.2. Draw-over type vaporizers are uncommon today, but remain an option for providing anesthesia in resource-poor environments.[68a] Variable bypass vaporizers carry additional designations such as agent-specific, flow-over, temperature-compensated, and pressure-compensated, which are discussed later.

Variable Bypass Vaporizers. When volatile anesthetic agents evaporate, their resultant saturated gas concentrations greatly exceed those used clinically, so these concentrations must be diluted to safe ranges (see Table 22.1). *Variable bypass* refers to the method of diluting gas fully saturated with anesthetic agent with a more voluminous flow of gas. A diagram of a variable bypass vaporizer is shown in Fig. 22.19. Basic vaporizer components include a vaporizer inlet port (fresh gas inlet), the concentration control dial, the bypass chamber, the vaporizing chamber, the vaporizer outlet port, and the filling assembly. The maximum safe level of the vaporizer corresponds to the filling port, which is positioned to minimize the chance of overfilling. A concentration control dial determines the ratio of gas that flows through the bypass chamber and the vaporizing chamber, and a temperature-compensating device further adjusts that ratio. Vaporizer concentration control dials are labeled to set vaporizer output in terms of volume percent (*v*/*v*%), and the vaporizers are calibrated at sea level.

Fig. 22.20 illustrates volatile anesthetic equilibrium concentrations within a theoretical vaporizing chamber of a variable bypass vaporizer. As can be seen, the saturated vapor concentration of sevoflurane within the chamber (21%) far exceeds the clinical concentration. Fig. 22.20 also depicts the volume of anesthetic vapor that is added to the gas stream as it flows through the chamber. These properties are essential for a quantitative understanding of variable bypass vaporizer function (Box 22.1). Although this example and others in the chapter imply that the gas flowing through the vaporizing chamber becomes fully saturated with anesthetic vapor, this is actually not the case. There is insufficient time to reach evaporative equilibrium due to the constant inflow of fresh gas. As a result, the vaporizing chamber becomes only partially saturated with volatile anesthetic.[69] However, for the purposes of this discussion, it is useful to assume that full saturation occurs.

TABLE 22.2 Concise Summary of Modern Vaporizer Nomenclature

Type	Subtype(s)	Characteristics
Variable bypass vaporizers		
	Plenum type	Out-of-circuit, high resistance, gas flow under positive pressure
	Draw-over type	In-circuit, low resistance, gas flow under negative pressure; may be portable
Cassette vaporizer	GE Aladin and Aladin2	Computer-controlled variable bypass vaporizer
Dual-circuit (desflurane) vaporizer	GE Tec 6 and Dräger D-Vapor	Gas-vapor blender, heated & pressurized
Injection vaporizer	Maquet and Dräger DIVA	Direct injection of volatile anesthetic
Anesthetic reflector	AnaConDa, Mirus	Adsorption to and release from a carbon filter

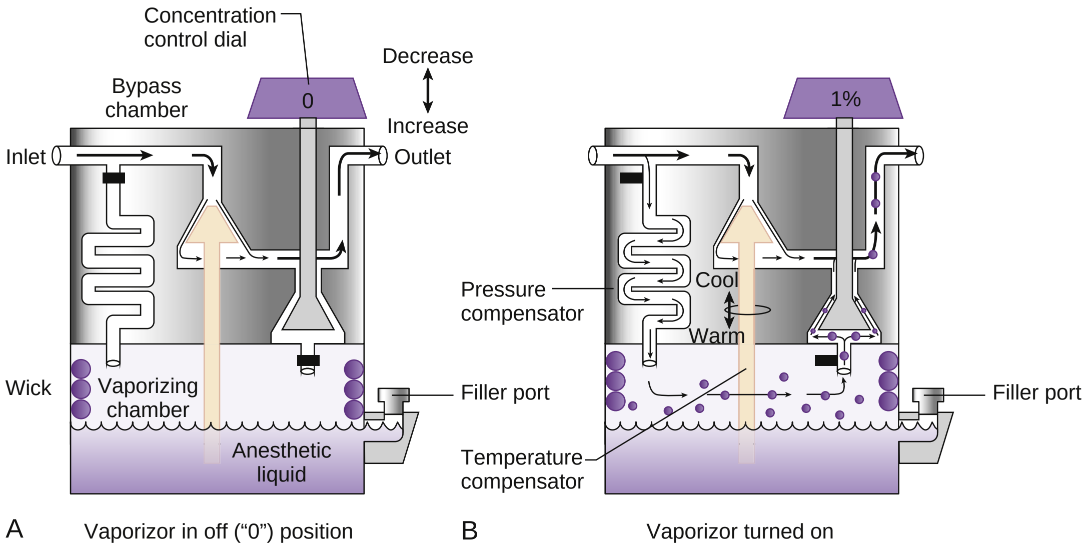


Fig. 22.19 Variable bypass vaporizer. (A) Basic components. Vaporizer in the off or "0" position. Fresh gas from the flowmeter assembly enters the vaporizer and then flows through the bypass chamber, around the temperature compensator, and out the vaporizer without passing through the vaporizing chamber. (B) Selecting a vaporizer output (turning the vaporizer "on") diverts an agent-specific ratio of gas through the pressure-compensating labyrinth, into the vaporizing chamber where it becomes saturated with anesthetic vapor, and then past the concentration cone where it reunites with the fresh gas stream. The temperature compensation device further adjusts the ratio of bypass to vaporizing chamber flow, to compensate for changes in anesthetic vapor pressure resulting from temperature changes. As the liquid anesthetic cools by evaporation, more gas is diverted to the vaporizing chamber to compensate for the decrease in vapor pressure. The labyrinth compensates for pressure fluctuations within the vaporizer from the gas supply side and the breathing circuit side to stabilize vaporizer output; it is *not* present to compensate for changes in atmospheric pressure. Please see text for additional details.

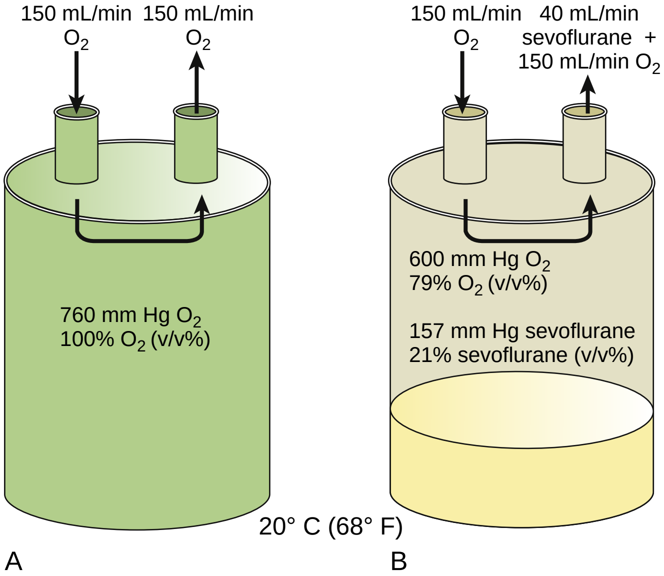

Fig. 22.20 Theoretical vaporizing chamber demonstrating the volume of anesthetic gas added to the gas flow stream as a result of evaporation: (A) Pure oxygen flows through the chamber. (B) Liquid sevoflurane is added to the chamber and evaporates to saturated vapor pressure (see Box 22.1 for details).

Fig. 22.21 illustrates a modern variable bypass vaporizer set to deliver 2% sevoflurane. Note how the majority of fresh gas flows straight through the bypass chamber. The bypass flow and vaporizing chamber output combine to create the desired output concentration. The fresh gas that is diverted to the vaporizing chamber becomes saturated with anesthetic gas by flowing through the wicks and over the liquid agent (hence the designation *flow-over*). The wicks and baffles serve to increase the surface area available for vaporization and promote mixing of the carrier gas with anesthetic vapor.[69a,69b] The specific ratio of fresh gas flow divided between the bypass chamber and the vaporizing chamber is determined by the concentration control dial setting and the temperature compensation device (see the later discussion of temperature compensation). Because the physical properties and clinical concentrations of each agent are unique, the diverting ratios are specific to each agent and dial setting (hence the designation *agent-specific*). The approximate variable bypass diverting or "splitting ratios" for the common anesthetic agents at 20°C are shown in Table 22.3. Variable bypass vaporizers cannot be used to deliver desflurane, because of this agent's unique physical properties (see section on the desflurane vaporizer).

Virtually all variable bypass vaporizers are equipped with a mechanism that helps maintain constant vaporizer output over a wide range of operating temperatures (hence the designation *temperature-compensated*). This mechanism automatically alters the ratio of gas flowing through the bypass and vaporizing chambers. Temperature compensation is accomplished by an expansion-contraction element, as seen in Fig. 22.19, or a bimetallic strip (Fig. 22.22). At cooler temperatures, the vapor pressure of liquid anesthetic decreases (Fig. 22.16), and it is necessary to reduce the splitting ratio to maintain output. In Fig. 22.19*B*, as the liquid anesthetic agent cools, the temperature-compensating cone moves upward, restricts bypass flow, and diverts more gas to the vaporizing chamber, thereby maintaining relatively stable vaporizer output. The inverse is also true: warmer temperatures cause the cone to move downward, increasing bypass flow, and diverting less gas to the vaporizing chamber. The most important function of temperature compensation devices is to correct for the effect of evaporative cooling on the liquid anesthetic.

BOX 22.1 Calculation of the Volume of Gas Added to a Fresh Gas Flow, and Proof of the Splitting Ratio

Step 1: Calculate the amount of volatile anesthetic added to the fresh gas stream that makes up a vaporizer chamber output.

- Assume that 150 mL/min of oxygen flows through a vaporizer chamber at 1 atm (760 mm Hg) pressure and 20°C (68°F) (Fig. 22.20*A*).
- Liquid sevoflurane is then added to the vaporizer chamber (Fig. 22.20*B*).
- Sevoflurane evaporates to its saturated vapor pressure (SVP) of 157 mm Hg, which displaces oxygen from the gas mixture. At this point, sevoflurane has a saturated vapor concentration (SVC) of 157 mm Hg/760 mm Hg ~21% (see Table 22.1).
- Sevoflurane makes up 21% of the gas flowing out of the vaporizer, and oxygen makes up 79%.
  - To calculate the amount of sevoflurane added to the fresh gas flow through the vaporizer, set up the simple proportion:
    - (*x* mL/min sevoflurane)/21% = (150 mL/min oxygen)/79%
  - Solve for *x*:
    - *x* = (150 mL/min) * 21%/79% ~ 40 mL/min sevoflurane
- Therefore 40 mL/min of sevoflurane is added to the vaporizer output, for a total of 190 mL/min (Fig. 22.20*B*).

Step 2: Prove the splitting ratio for a variable bypass vaporizer.

Building on the example in **Step 1**, consider a sevoflurane vaporizer with 2000 mL/min of fresh gas inflow. Prove that the splitting ratio must be ~12:1 in order to deliver 2% sevoflurane.

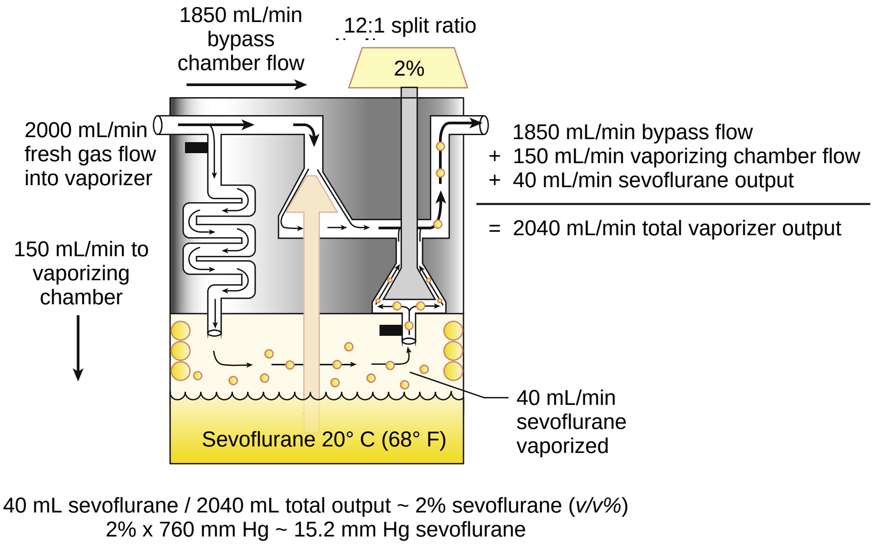
- A splitting ratio of 12:1 means that ~150 mL/min of fresh gas is diverted to the vaporizer chamber, and ~1850 mL/min flows through the bypass chamber (see Fig. 22.21).
- 40 mL/min of sevoflurane is added to the vaporizer output (see **Step 1**).
- The total vaporizer output is 2040 mL/min.
- Sevoflurane makes up (40 mL/min)/(2040 mL/min) ~2% of the total vaporizer output.

Variable bypass vaporizers are also constructed from materials with high specific heat, yielding temperature stability, and high thermal conductivity, which allows rapid transfer of ambient heat. Additionally, the vaporizer wick systems are located in contact with the metal walls to facilitate absorption of environmental heat.

FACTORS THAT INFLUENCE VARIABLE BYPASS VAPORIZER OUTPUT. An ideal variable bypass vaporizer would maintain a constant concentration output at a given setting regardless of variables such as the fresh gas flow rate, temperature, intermittent backpressure from the breathing circuit, carrier gas composition, and barometric pressure. ISO standards state that the average output should not deviate from the dial setting by +30% or −20% or more than +7.5% or −5% of the maximum setting.[11] Although modern vaporizers generally have excellent performance characteristics, it is important to understand how these challenges could potentially influence vaporizer output.

IMPACT OF GAS FLOW RATE. This factor is notable only at the extremes of flow rates and at higher concentration control dial settings. At low flow rates (<250 mL/min), the output tends to be slightly less than the dial setting due to the relatively high density of volatile anesthetic agents. Insufficient turbulence is generated in the vaporizing chamber to advance the vapor molecules upward. At high flow rates (such as 15 L/min), the output of most variable bypass vaporizers is somewhat less than the dial setting. This discrepancy is due to: cooling during rapid evaporation, incomplete mixing, and failure to saturate the carrier gas in the vaporizing chamber. In addition, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases.[68,70]

IMPACT OF TEMPERATURE CHANGE. Despite the impact of evaporative cooling and variation in ambient conditions, modern vaporizers maintain fairly constant concentration output over a wide range of common working temperatures. However, the linear change in the temperature-compensating mechanisms does not precisely match the shape of the



1850 mL/min bypass chamber flow
12:1 split ratio

v/v%, Volume percent.

vapor pressure curves.[19,68] As a result, a slight correlation between vaporizer temperature and delivered concentration remains. This correlation is mainly apparent at higher temperatures and higher concentrations (Fig. 22.23). A dangerous but highly unlikely circumstance could occur if the boiling point of a volatile agent within a variable bypass vaporizer were reached. In this situation, the vaporizer output would be impossible to control by any compensatory mechanism. Although it would be rare to reach ambient temperatures around 50°C at sea level (see Table 22.1), at higher altitudes, where boiling points are lower, this is theoretically more likely. In fact, the Dräger Vapor 2000 user's manual decreases the high-altitude operating specification for the vaporizer from 9880 to 4800 feet if halothane or isoflurane is used at higher ambient temperatures. Manufacturers' published vaporizer operating temperatures range from 10°C to 40°C (50°F-104°F), although the specific ranges vary.[68,70-74]

IMPACT OF INTERMITTENT BACKPRESSURE. The intermittent backpressure that results from either positive-pressure ventilation or use of the oxygen flush valve may lead to higher than expected vaporizer output. This phenomenon, known as the *pumping effect*, is more pronounced at low flow rates, low dial settings, and low levels of liquid anesthetic in the vaporizing chamber.[44,68,75-77] Additionally, the pumping effect is increased by rapid respiratory rates, high peak inspiratory pressures (PIPs), the use of anesthesia machines without fresh gas decoupling, and rapid drops in pressure during expiration.[44,59,67,68,78,79] Although contemporary variable bypass vaporizers are not highly vulnerable to the pumping effect, the proposed mechanism and preventative design features should be understood. The pumping effect is caused by retrograde transmission of pressure from the patient circuit to the vaporizer during the inspiratory phase of positive-pressure ventilation or use of the oxygen flush function. Gas molecules are compressed in both the bypass and vaporizing chambers. When the backpressure is suddenly released during the expiratory phase, vapor exits the vaporizing chamber both antegrade through the outlet and retrograde through the inlet. This occurs because the output resistance of the bypass chamber is lower than that of the vaporizing chamber, particularly at low dial settings. The enhanced output concentration results from the increment of vapor that travels in the retrograde direction to the bypass chamber.[68,76,77,80]

To decrease the pumping effect, modern vaporizing chambers are smaller than those of early variable bypass vaporizers so that only a small volume of vapor can be discharged retrograde into the bypass chamber.[77] Additionally, some vaporizers have a long spiral tube or labyrinth that serves as the inlet to the vaporizing chamber (see Fig. 22.19).[77] When the pressure in the vaporizing chamber is released, the vapor does not flow back into the bypass chamber because of tube length.[59] This serpentine passage also dampens pressure fluctuations and compensates for fluctuations in gas supply pressure. Other designs may also include an extensive baffle system in the vaporizing chamber. Finally, a one-way check valve can be inserted after the vaporizers and before the breathing circuit inlet to minimize the pumping effect (see the discussion of the gas supply system). This check valve can attenuate but does not eliminate the increase in pressure, because gas still flows from the flowmeters to the vaporizer during the inspiratory phase of positive-pressure ventilation.[44,81] Although intermittent backpressure can result in transient rises in anesthetic concentration at the common gas outlet, the effects are mitigated by dilution within the much larger anesthetic breathing circuit.[82] The goal of all these pressure-compensating mechanisms is to provide an even flow of gas through the vaporizing chamber despite changes in pressure, giving the vaporizers the additional designation *pressure-compensated*.

IMPACT OF CARRIER GAS COMPOSITION. Variable bypass vaporizer output can be influenced by fresh gas composition. This phenomenon is the result of differences in the solubility of carrier gases in volatile anesthetic liquids. This effect is most pronounced when nitrous oxide is introduced or removed as a carrier gas.[68,83-90] In the experimental example seen in Fig. 22.24, a change in carrier gas from 100% oxygen to 100% nitrous oxide results in a sudden decrease in halothane output (expressed as volume percent) followed by a slow increase to a new, lower, steady-state (see Fig. 22.24, label *B*).[88,89] Because nitrous oxide is more soluble than oxygen in the liquid anesthetic within the vaporizer sump, more of the carrier gas dissolves, and the volume output from the vaporizing chamber is transiently reduced.[88] Once the anesthetic liquid becomes saturated with nitrous oxide, the vaporizing chamber output increases and achieves a new steady state.

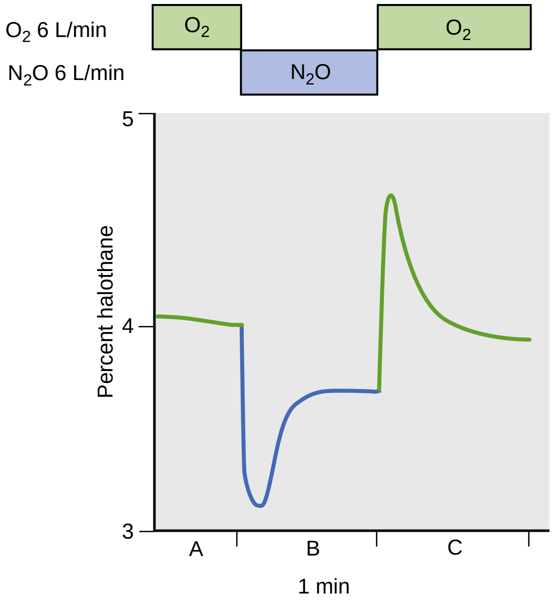

Fig. 22.24 Halothane output of a North American Dräger Vapor 19.n vaporizer (Dräger Medical, Telford, PA) with different carrier gases. The initial output concentration is approximately 4% halothane when oxygen is the carrier gas at flows of 6 L/min *(A)*. When the carrier gas is quickly switched to 100% nitrous oxide *(B)*, the halothane concentration decreases to 3% within 8 seconds. A new steady-state concentration of approximately 3.5% is then attained within about 1 minute. When O_2 flow is reestablished, halothane output increases abruptly and then settles back to baseline *(C)*. See text for details. (Modified from Gould DB, Lampert BA, MacKrell TN. Effect of nitrous oxide solubility on vaporizer aberrance. *Anesth Analg.* 1982;61:939.)

The explanation for the new steady-state output value is less well understood.[90] Differences in density and viscosity between oxygen and nitrous oxide are likely responsible[90a] because these physical properties affect the relative amount of gas flow through the bypass and vaporizing channels.[86,89,91] Helium, a gas with far lower density than either oxygen or nitrous oxide, has been shown to have variable effect on vaporizer output, depending on the vaporizer model and study design (although the changes tend to be minimal).[92,93]

Although the carrier gas composition can be demonstrated experimentally to affect vaporizer output, deviations are often within specified accuracy ranges. Vaporizer user's manuals usually specify the anticipated response to a change in carrier gas relative to the calibration gas, which may be air or oxygen, depending on the vaporizer model.[68,70,71,94]

IMPACT OF BAROMETRIC PRESSURE CHANGES. Understanding the influence of barometric pressure on variable bypass vaporizer output is probably more important for comprehending vaporizer function than for actual clinical reasons. With variable bypass vaporizers, the depth of anesthesia at a given dial setting is relatively independent of atmospheric pressure, and no adjustments need to be made (Table 22.4).[68]

TABLE 22.4 Comparative Performance of an Isoflurane Variable Bypass Vaporizer and the Tec 6 Desflurane Vaporizer During Changes in Barometric Pressure

		Isoflurane Variable Bypass Vaporizer With Dial Setting of 0.89% (v/v)			Tec 6 Desflurane Vaporizer With Dial Setting of 6%
Atm	**Ambient Pressure (mm Hg)**	**mL Isoflurane Vapor Entrained by 100 mL O_2**	**Vaporizer Isoflurane Output (v/v%)**	**Vaporizer Isoflurane Output (mm Hg)**	**Vaporizer Desflurane Output (mm Hg)**
0.66	500 (≈10,000 ft)	91	1.7	8.8	30
0.74	560 (≈8200 ft)	74	1.5	8	33.6
0.8	608 (≈6000 ft)	64	1.2	7.6	36.5
1.0	760 (sea level)	46	0.89	6.8	45.6
1.5*	1140	26	0.5	5.9	68.4

3*	2280	12	0.23	5.2	136

*ATA or *atmospheres absolute*. ATA = *atmospheric pressure* + *water pressure*. Hyperbaric oxygen chamber protocols apply ATA. Many protocols use depths from 2.0 to 2.5 ATA, but some conditions such as gas embolus or carbon monoxide poisoning may require depths to 3.0 ATA.[238] 2 ATA ≈ 33 feet of sea water (fsw) ≈ 1520 mm Hg *ambient pressure*.

atm, Atmospheres (1 atm = 760 mm Hg); *v/v%,* volume percent.

Modified from Ehrenwerth J, Eisenkraft J. Anesthesia vaporizers. In: Ehrenwerth J, Eisenkraft J, eds. *Anesthesia Equipment: Principles and Applications*. St. Louis: Mosby; 1993:69–71.

HIGHER ALTITUDE. As previously discussed, vapor pressure is independent of barometric pressure. Therefore as altitude increases and barometric pressure declines, the partial pressure of anesthetic agent in the vaporizing chamber remains constant despite decreases in the partial pressures of other constituent breathing gases and the total ambient pressure. This situation results in significantly increased volume percent concentration of anesthetic agent within the vaporizing chamber and at the outlet of the vaporizer (see Table 22.4). However, because anesthetic depth is determined by the *partial pressure* of volatile agent in the brain, the clinical impact is minor (see MAPP in Table 22.1).

Let us consider an example of moving a vaporizer from sea level to higher altitude. With a constant dial setting of 0.89%, at 1 atm, a well-calibrated isoflurane variable bypass vaporizer would deliver 0.89 *v*/*v*% isoflurane, and the partial pressure of isoflurane output would be 6.8 mm Hg. Assume that we maintain the same dial setting and lower the atmospheric pressure to 0.66 atm or 502 mm Hg (roughly equivalent to an elevation of 10,000 feet. This results result in an increase in the isoflurane concentration output to 1.75% (a 97% increase), but the partial pressure increases to only 8.8 mm Hg (a 29% increase). A similar change in output partial pressure at sea level, in terms of volume percent, would correspond to an isoflurane concentration increase of only 0.2%. So while the anesthetic concentration (*v*/*v*%) changes significantly in this example, it is the partial pressure of volatile agent in the brain that is ultimately responsible for anesthetic depth, and that change is minimal.

As described earlier, MAC values for contemporary inhalational anesthetic agents were determined at sea level. Similarly, anesthetic vaporizers are calibrated at sea level, thus ensuring that vaporizer output (*v*/*v*%) matches the dial setting. Using the isoflurane data shown in Table 22.4 as an example, one can see how confusion may arise when thinking of MAC in terms of volume percent and considering barometric change.

The MAPP at altitude is the same as at sea level because it is a partial pressure, whereas the MAC increases because it is a simple concentration. Table 22.4 shows that the *partial pressure output* of a variable bypass vaporizer changes proportionally less than the volume percent concentration as altitude increases. Because the partial pressure of volatile agent determines anesthetic depth, the operator *does not* need to adjust the dial to a higher setting to compensate for barometric pressure. This holds true for variable bypass vaporizers, but not for the desflurane Tec 6–style vaporizer (see later).

HYPERBARIC CONDITIONS. Although anesthesia is sometimes delivered in *hyperbaric conditions*, intravenous anesthesia is easier to deliver in this setting. Under hyperbaric conditions, the partial pressure of volatile anesthetic in the vaporizing chamber remains constant despite an increase in ambient pressure and the partial pressure of the other gases. The net theoretical effects on variable bypass vaporizers are a significant decrease in anesthetic concentration (*v*/*v*%) and a mild decrease in partial pressure output. However, the partial pressure of halothane was noted to increase slightly with increasing barometric pressure under experimental conditions.[95] Possible explanations for this finding include the effect of increased atmospheric gas density on the flow of gas through the vaporizer and the increased thermal conductivity of air at higher pressure. The clinical significance of these small changes in partial pressure output under hyperbaric conditions is unclear.

OTHER SAFETY FEATURES. Contemporary variable bypass vaporizers incorporate many other safety features. Agent-specific, keyed filling devices help prevent filling with the wrong agent. Overfilling is minimized by locating the filler port at the maximum safe liquid level. Modern vaporizers are firmly secured to a manifold on the anesthesia workstation to prevent tipping. Contemporary interlock systems prevent the administration of more than one inhaled anesthetic agent. However, virtually all safety systems have vulnerabilities, so it remains important to understand these potential hazards.

MISFILLING. Misfilling of anesthetic vaporizers with the wrong agent can result in an overdose or underdose of volatile anesthetic.[96,97] Vaporizer output in these circumstances depends on the erroneous agent's saturated vapor pressure and the splitting ratio of the misfilled vaporizer, since these key parameters must normally be matched to ensure accurate agent delivery (see earlier discussion). Similarly, mixtures of anesthetic agents can also result in harmful dosing.[60] Agent-specific filling devices have reduced, but not eliminated, misfilling. The potential for misfilling exists even in vaporizers equipped with keyed fillers,[98-100] and current standards do not mandate their use.[20] The use of breathing circuit gas analysis may alert the user to misfilling. If a variable bypass vaporizer for isoflurane or sevoflurane is misfilled with desflurane, a substantial overdose could occur because of the high vapor pressure of desflurane (see Fig. 22.16).

CONTAMINATION. Although rarely reported, contamination of anesthetic vaporizer contents has occurred. In one instance, organic contaminants (some volatile) in a bottle of isoflurane were detected because of an abnormal acrid odor emanating from the vaporizer.[101] In another report, water accumulation within sevoflurane vaporizers allowed bacteria *(Staphylococcus epidermidis)* to grow and metabolize liquid sevoflurane to volatile and potentially toxic compounds.[101a]

TIPPING. Tipping of a variable bypass vaporizer can occur when it is incorrectly removed, transported, or replaced. Excessive tipping can allow the liquid agent to enter the bypass chamber and cause an extremely high output.[102] Although some vaporizers are more sensitive than others, most should not be used after tipping until they have been flushed for a period of time at high flow rates. Manufacturers' instructions differ regarding their post-tipping procedures, so it is best to refer to each specific user manual.[68,70,71,94] A gas analyzer should be used to assess vaporizer output before replacing into clinical use. The Dräger Vapor and D-Vapor series vaporizers have a transport ("T") dial setting that isolates the vaporizer chamber from the bypass chamber to eliminate the possibility of internal overflow during transport.[68]

OVERFILLING. Improper filling procedures, combined with failure of the vaporizer sight glass, can cause patient overdose. If overfilled, liquid anesthetic may enter the bypass chamber, and a harmful dose of vapor could be delivered to the common gas outlet.[103] It is a requirement that contemporary vaporizers be designed so that they cannot be overfilled when they are used in a normal operating position.[20] Side-fill variable bypass vaporizers, as opposed to top-fill devices, largely prevent overfilling because the maximum safe level is predetermined by the position of the filler port (see Fig. 22.19). In addition, some vaporizers are equipped with an overflow hole as an additional safeguard.[68] Overfilling can still occur if the vaporizer is tipped or turned on while filling, or air enters at the bottle neck and filler adapter caused by a loose or faulty seal.[103-106]

LEAKS. Vaporizers and the vaporizer-machine interface are potential sources of gas leaks that can result in patient awareness during inhaled anesthesia. Loose filler caps, filler plugs, and drain valves are probably the most common sources of leaks. Such a leak may be obvious (e.g., an audible gas leak with spillage of anesthetic agent) or have a more subtle presentation (such as a lower than expected inhaled agent concentration, or the odor of anesthetic gas).[107,108] Another common source of gas leak occurs at the junction of the vaporizer and the mounting bracket or manifold, where broken mounting assemblies or foreign bodies can compromise the seal between the vaporizer and its point of attachment.[109-112] Gas leaks can also occur within the vaporizer itself as a result of mechanical failure.

ENVIRONMENTAL CONSIDERATIONS. Anesthesia delivery has become more common outside the operating rooms, and one challenging location is the magnetic resonance imaging (MRI) suite. The presence of a powerful magnetic field, significant noise pollution, and limited access to the patient during the procedure all complicate care in this setting. The anesthesia provider must appreciate the extremely powerful magnetic fields in these locations and know that only nonferrous (MRI-compatible) equipment can be used. Although some anesthesia vaporizers may appear nonferrous by testing with a horseshoe magnet, they may indeed contain substantial internal ferrous components. Inappropriate use of such devices in an MRI suite may turn them into dangerous missiles if left unsecured.[113]

Desflurane Vaporizer. Because of its unique physical characteristics, accurate delivery of desflurane required a different approach to vaporizer design. The Datex-Ohmeda Tec 6 vaporizer was released into clinical use in the early 1990s. The Tec 6 is an electrically heated, pressurized device specifically designed to deliver desflurane (Fig. 22.25).[114,115] Dräger Medical received approval from the U.S. Food and Drug Administration (FDA) for the D-Vapor, its version of the desflurane vaporizer in 2004. The operating principles apply to either system, although the discussion refers to the Tec 6 specifically. The Datex-Ohmeda Aladin cassette vaporizer and the Maquet vaporizers are discussed separately because their operating principles are different.

UNSUITABILITY OF CONTEMPORARY VARIABLE BYPASS VAPORIZERS FOR CONTROLLED VAPORIZATION OF DESFLURANE. Desflurane's high volatility and moderate potency (see Table 22.1) preclude its use with contemporary variable bypass vaporizers for three main reasons[114]:

1. *Desflurane's high rate of evaporation would require excessive diluting gas (bypass chamber) flow.* The vapor pressure of desflurane is 669 mm Hg at 20°C (68°F), which is significantly higher than other inhaled anesthetic agents (see Fig. 22.16).[116] At 1 atm and 20°C, 100 mL/min passing through the vaporizing chamber would entrain 735 mL/min of desflurane (as compared with 29, 46, and 47 mL/min of enflurane, isoflurane, and halothane, respectively).[114] To produce a 1% desflurane output, the amount of bypass flow required to dilute the large volume of desflurane-saturated anesthetic vapor would be approximately 73 L/min (in contrast to 5 L/min or less for the other three agents). Prohibitively high bypass chamber flow rates would be required to dilute the vaporizing chamber output to clinical concentrations.
2. *Desflurane's high rate of evaporation would cause substantial anesthetic cooling.* Variable bypass vaporizers require ambient heat to offset evaporative cooling. Although the latent heat of vaporization for desflurane

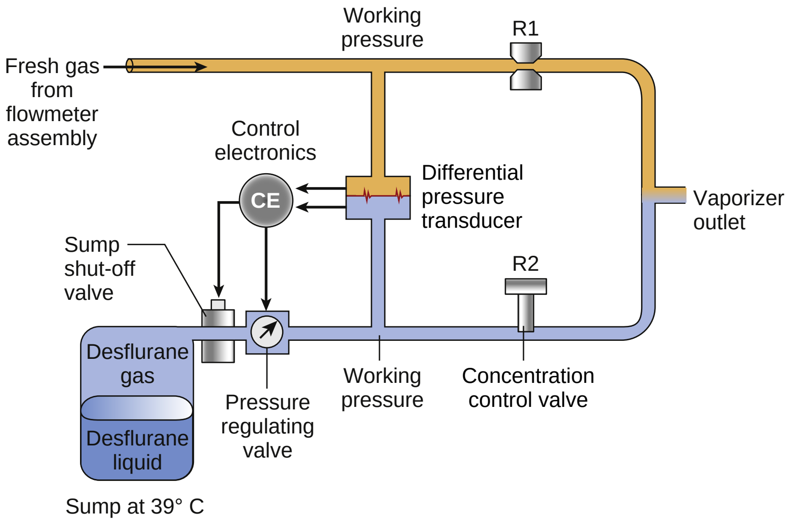

Fig. 22.25 Simplified schematic of the Tec 6 desflurane vaporizer (Datex-Ohmeda, Madison, WI). See text for details. (From Andrews JJ. *Operating Principles of the Ohmeda Tec 6 Desflurane Vaporizer: A Collection of Twelve Color Illustrations.* Washington, DC: Library of Congress; 1996.)

is approximately equal to that of enflurane, isoflurane, and halothane, its MAC is much higher. The amount of desflurane required to be vaporized over a given period is considerably greater than that of the other inhaled anesthetics. Supplying desflurane in equivalent MAC concentrations would lead to excessive cooling of the vaporizer and reduced output without an external heat source. Because of the broad range of temperatures seen in the clinical setting and desflurane's steep vapor pressure–versus-temperature curve (see Fig. 22.16), desflurane delivery would not be stable in a conventional variable bypass vaporizer.[114]

3. *Desflurane is more likely to boil.* The boiling point of desflurane is 22.8°C (73°F) at 1 atm. This temperature is at the higher end of normal operating room temperatures. If the anesthetic agent were to boil within a variable bypass–type vaporizer, the output would be uncontrollable. The amount of vapor produced would be limited only by heat transfer to the desflurane liquid, which depends upon the specific heat and thermal conductivity of the vaporizer (see discussion above).[114]

OPERATING PRINCIPLES OF THE TEC 6 AND TEC 6 PLUS. The Tec 6 desflurane vaporizer was the first clinically available vaporizer to be electrically heated and pressurized, making many aspects of the internal design and operating principles radically different from variable bypass vaporizers, The Tec 6 is probably more accurately described as a dual-gas blender than as a vaporizer. A simplified schematic of the Tec 6 is shown in Fig. 22.25. The vaporizer has two independent gas circuits arranged in parallel. The fresh gas circuit is shown in *orange*, and the vapor circuit is shown in *blue.* Fresh gas from the flowmeters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is a reservoir of desflurane vapor. It is electrically heated to 39°C, a temperature much higher than desflurane's boiling point. At 39°C, the vapor pressure in the sump is approximately 1300 mm Hg (~2 atm).[117] Just downstream from the sump is the shut-off valve. After the vaporizer warms up, the shut-off valve fully opens when the concentration control valve is turned to the "on" position.

TABLE 22.5 Fresh Gas Flow Rate Versus Working Pressure in the Tec 6 Desflurane Vaporizer

Fresh Gas Flow Rate (L/min)	Working Pressure at R1 and R2 (mm Hg)
1	7.4
5	37.0
10	74.0

From Andrews JJ, Johnston RV Jr. The new Tec 6 desflurane vaporizer. *Anesth Analg.* 1993;76:1338.

A pressure-regulating valve located downstream from the shut-off valve down regulates the pressure to the pressure of the background gas. The operator controls the output of desflurane by adjusting the concentration control valve (R2), which is a variable restrictor.[114]

The vapor flow through R2 joins the fresh gas flow through R1 at a point downstream from the restrictors. Until this point, the two circuits are physically separated. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When fresh gas flows past the fixed restrictor R1, a specific backpressure proportional to the flow rate pushes against the diaphragm of the differential pressure transducer. The transducer relays the pressure difference between the fresh gas circuit and the desflurane vapor circuit to the control electronics system. The control system tunes the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, which is constant at a fixed fresh gas flow rate. If the operator increases the fresh gas flow rate, more backpressure will be exerted on the diaphragm of the pressure transducer, and the working pressure of the vaporizer will increase.[114] Table 22.5 shows the linear relationship between fresh gas flow rate and working pressure for a typical Tec 6 vaporizer.

The following are two specific examples to demonstrate the operating principles of the Tec 6:[114]

TABLE 22.6 Dial Setting Versus Flow Through Restrictor R2 at 1 L/min Fresh Gas Flow in the Tec 6 Desflurane Vaporizer

Dial Setting (vol%)	Approximate Vapor Flow Rate Through R2 (mL/min)
1	10
6	64
12	136
18	220

From Andrews JJ, Johnston RV Jr. The new Tec 6 desflurane vaporizer. *Anesth Analg*. 1993;76:1338.

Example A: *Constant fresh gas flow rate of 1 L/min with an increase in the dial setting.* With a fresh gas flow rate of 1 L/min, the pressure supplying R1 and R2 is 7.4 mm Hg. As the operator increases the dial setting, the opening at R2 becomes larger, thereby allowing more vapor to pass through R2. Specific vapor flow values at different dial settings are shown in Table 22.6.

Example B: *Constant dial setting with an increase in fresh gas flow from 1 to 10 L/min.* At a fresh gas flow rate of 1 L/min, the working pressure is 7.4 mm Hg, and at a dial setting of 6%, the vapor flow rate through R2 is 64 mL/min (see Tables 22.5 and 22.6). With a 10-fold increase in the fresh gas flow rate, the working pressure increases to 74 mm Hg. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases 10-fold to 640 mL/min. Both fresh gas flow and vapor flow increase proportionally, so vaporizer output is constant.

FACTORS THAT INFLUENCE TEC 6 DESFLURANE VAPORIZER OUTPUT. Barometric pressure and carrier gas composition influence the Tec 6 vaporizer output.

HIGHER ALTITUDE. Although ambient pressure changes affect the volume percent output of *variable bypass vaporizers* significantly, the effect on partial pressure output is minimal (and recall that the partial pressure of volatile agent in brain tissue is the main determinant of anesthetic depth). By contrast, the partial pressure output of Tec 6 style desflurane vaporizers is significantly affected by altitude, as can be seen in Table 22.4. One must remember that the Tec 6 device is more accurately described as a dual-gas blender than a vaporizer. Regardless of ambient pressure, the Tec 6 will maintain a constant volume percent output (*v*/*v*%), *not a constant partial pressure*. This means that at high altitudes, the partial pressure of desflurane will decrease in proportion to the reduction in atmospheric pressure divided by the calibration pressure (normally 760 mm Hg) per the following formula:

$$\text{Required dial setting } (\%) = \text{Normal dial setting} \times (760 \text{ mm Hg}) \;/\; [\text{Ambient pressure (mm Hg)}]$$

For example, at an altitude of 2000 m, or 6564 feet, where the ambient pressure is 608 mm Hg, the operator must advance the concentration control dial from 10% to 12.5% to maintain the required anesthetic partial pressure. In hyperbaric settings, the operator must decrease the dial setting to prevent delivery of an overdose. At 2 atm or 1520 mm Hg of pressure, the desflurane output in mm Hg is twice that at sea level (91.2 vs. 45.6 mm Hg).

CARRIER GAS COMPOSITION. Vaporizer output most closely matches the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated with 100% oxygen. When a carrier gas other than 100% oxygen is used at low flow rates, a clear trend toward reduction in vaporizer output emerges. This reduction correlates with the decrease in viscosity of the carrier gas. Nitrous oxide is less viscous than oxygen, and generates lower backpressure upstream of resistor R1 (see Fig. 22.25). As a result, the working pressure is reduced. At low flow rates with nitrous oxide as the carrier gas, vaporizer output is approximately 20% less than the dial setting.

SAFETY FEATURES. Because desflurane's vapor pressure is nearly 1 atm, misfilling a variable bypass vaporizer with desflurane could theoretically result in both overdose and creation of a hypoxic gas mixture. Like most of its contemporaries, the desflurane vaporizer has a unique, anesthetic-specific filling system to minimize this potential hazard. Each desflurane bottle has a "SAF-T-FILL" adapter intended to prevent use with traditional vaporizers. The SAF-T-FILL is essentially a spring-loaded valve that seals the bottle until the bayonet fitment is fully engaged in the filler port of a desflurane vaporizer.[119] This mechanism also helps guard against evaporative loss of agent during storage. The adapter has an O-ring on the tip to minimize spillage during filling.[119a] Thus the SAF-T-FILL system helps prevent both misfilling of variable bypass vaporizers and leakage of desflurane to the atmosphere.[119b]

Major vaporizer faults cause the shut-off valve located just downstream from the desflurane sump (see Fig. 22.25) to close and terminate output. The valve closes, and a no-output alarm is activated, if any of the following conditions occur: (1) the anesthetic level decreases to less than 20 mL, (2) the vaporizer is tilted, (3) a power failure occurs, or (4) the pressure difference between the vapor and fresh gas circuits exceeds a specified tolerance. Although such automated safeguards can enhance patient safety, they may have unintended consequences. For example, a previous generation of Datex-Ohmeda D-Tec Plus vaporizer was reported to be incompatible with a certain model of Dräger anesthesia machine.[120] By design, this workstation interrupted fresh gas flow during the inspiratory phase of volume control ventilation as a means of fresh gas decoupling. These purposeful fresh gas flow interruptions caused an alarm and inappropriate termination of vaporizer output. Although the vaporizer was subsequently modified, this example serves as a reminder that new technology can bring about new problems.

SUMMARY. The Tec 6 and Dräger D-Vapor vaporizers are electrically heated, thermostatically controlled, constant-temperature, pressurized, electromechanically coupled dual-circuit, gas vapor blenders. The pressure in the vapor circuit is electronically regulated to equal the pressure in the fresh gas circuit. At a constant fresh gas flow rate, the operator regulates vapor flow with a conventional concentration control dial. When the fresh gas flow rate increases, the working pressure increases proportionally. For a given concentration setting, even when varying the fresh gas flow rate, the vaporizer output is constant because the amount of flow through each circuit remains proportional.[114]

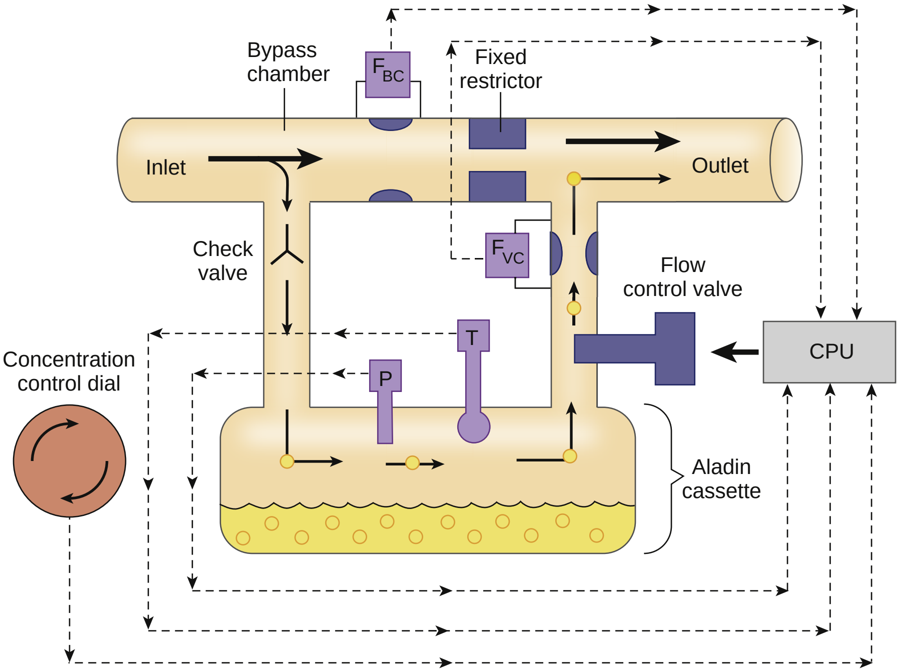

Fig. 22.26 Simplified schematic of Datex-Ohmeda Aladin cassette vaporizer (Datex-Ohmeda, Madison, WI). The black arrows inside the vaporizer represent flow from the flowmeters, and the yellow circles represent anesthetic vapor. The heart of the vaporizer is the electronically controlled flow control valve located in the outlet of the vaporizing chamber. *CPU,* Central processing unit; *F_{BC},* flow measurement unit that measures flow through the bypass chamber; *F_{VC},* flow measurement unit that measures flow through the vaporizing chamber; *P,* pressure sensor; *T,* temperature sensor. Please see text for additional details. (Modified from Andrews JJ. *Operating Principles of the Datex-Ohmeda Aladin Cassette Vaporizer: A Collection of Color Illustrations.* Washington, DC: Library of Congress; 2000.)

GE/Datex-Ohmeda Aladin and Aladin2 Cassette Vaporizers. The vaporizer system used in the GE Aisys anesthesia workstations (and some former Datex-Ohmeda models) is unique in that a single electronically controlled vaporizer is designed to deliver several different inhaled anesthetic agents. The vaporizer consists of a permanent internal control unit housed within the workstation and interchangeable cassettes that contain anesthetic liquid and serve as vaporizing chambers. The Aladin cassettes (now superseded by the Aladin2) are filled using agent-specific fillers and color-coded: red (halothane), orange (enflurane), purple (isoflurane), yellow (sevoflurane), and blue (desflurane). They are also magnetically coded to allow the anesthesia workstation to identify which cassette has been inserted.

Operationally, the Aladin cassette vaporizing system is best described, during most circumstances, as a computer-controlled variable bypass vaporizer (Fig. 22.26). It consists of a bypass section and vaporizing chamber, the latter of which is contained within the interchangeable cassette (Fig. 22.27). A fixed restrictor located in the bypass chamber causes gas flow from the inlet to split into two streams. One stream passes through the bypass chamber, and the other is diverted to the vaporizing chamber where it passes through a one-way check valve. This valve prevents retrograde flow of anesthetic vapor into the bypass chamber, and its presence is unique to the Aladin system. The one-way check valve is essential for precise delivery of desflurane (see below). Failure of the check valve to close can result in anesthetic overdose due to retrograde flow into the bypass chamber.

Within the cassette, anesthetic agent vaporizes freely to saturated vapor pressure. A flow control valve, modulated by a central processing unit (CPU), precisely meters the amount of gas flow through the vaporizing chamber, which then rejoins the bypass flow.[44] The CPU receives input from multiple sources: the concentration control dial, pressure and temperature sensors inside the vaporizing chamber, and flow sensors in the bypass and vaporizing chambers. The CPU also receives input from the flowmeters regarding the carrier gas composition, which can affect vaporizer output as described above. Using these data, the CPU precisely regulates fresh gas flow through the vaporizing chamber to obtain the desired vapor concentration output.[121]

As mentioned in the discussion of the Tec 6, controlled vaporization of desflurane presents a unique challenge, particularly when room temperature is higher than the boiling point (22.8°C [73°F]). If the desflurane were to boil, the pressure inside the vaporizing chamber would exceed ambient pressure. When vaporizing chamber pressure exceeds that in the bypass chamber, the one-way check valve closes and prevents carrier gas from entering the cassette. Carrier gas passes straight through the bypass chamber and its flow sensor. Under these conditions, the CPU adjusts the flow control valve to meter in the appropriate flow of pure desflurane vapor needed to achieve the desired final concentration. The vaporizer then begins functioning as an injector, as opposed to resembling a variable bypass unit.

During delivery of inhaled agents at high fresh gas flow rates and/or high dial settings, large quantities of anesthetic liquid are rapidly vaporized. As a result, the temperature of the vaporizer sump decreases due to evaporative

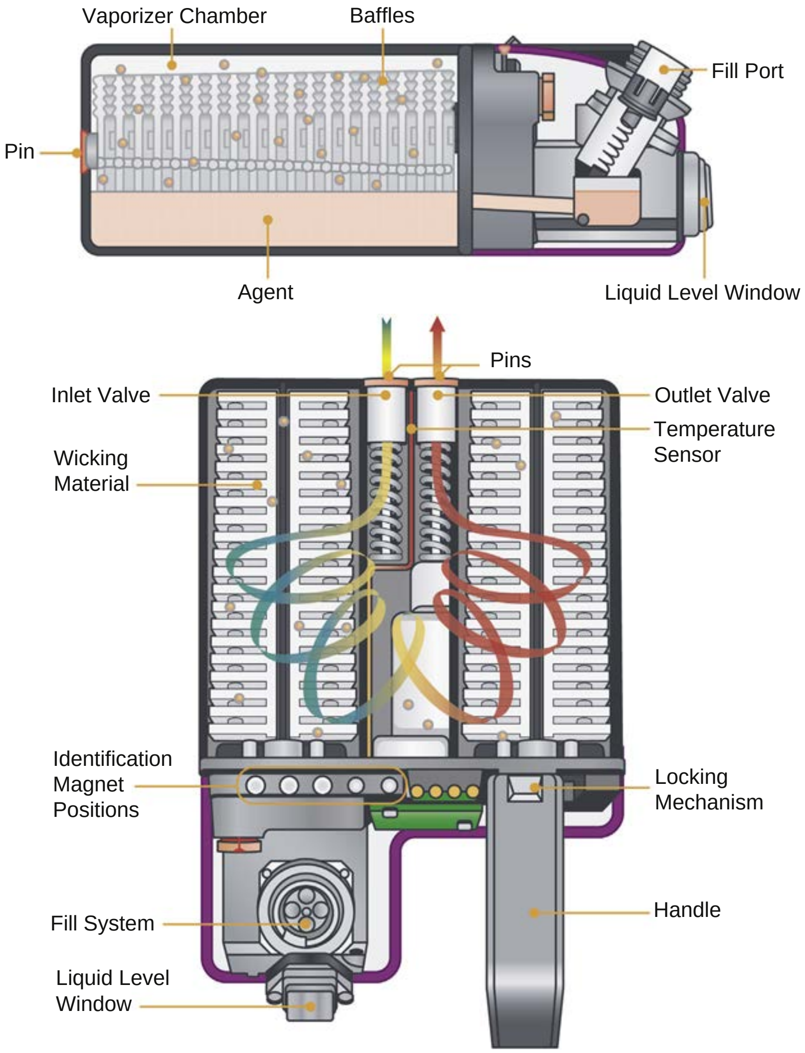

Fig. 22.27 Gas flow and safety features of the Aladin2 cassette. Top, side view illustrating filling system and baffles. Bottom, top view showing safety features, wicks, and gas flow during vapor uptake. (From GE HealthCare.)

cooling. To offset this cooling effect, some workstations are equipped with a fan that forces warmed air from a resistor across the cassette to raise its temperature when necessary. The fan is activated during two common clinical situations: (1) desflurane induction and maintenance and (2) sevoflurane induction.

The Aladin vaporizing system incorporates many important safety features. Electronic control of the carrier gas ratio guards against delivery of a hypoxic gas mixture. This ensures that no less than 25% oxygen is delivered at the common gas outlet regardless of carrier gas composition *and* concentration of anesthetic agent. This feature is unique, since conventional oxygen–nitrous oxide proportioning systems are not affected by the concentration of potent inhaled anesthetic agents. The system is also equipped with a safety relief valve that opens when cassette pressure exceeds 2.5 atm (1899 mm Hg). When the Aladin cassette is removed from the workstation, valves close to prevent loss of fresh gas. Another valve prevents liquid anesthetic from entering the fresh gas line. The system also has an overfilling protection mechanism.[121a] Finally, the Aladin cassette is immune to tipping and has no restrictions on orientation during handling or storage.[121]

Injection-Type Vaporizers: Maquet and Dräger Direct Injection of Volatile Anesthetic. The Maquet vaporizer is an electronically controlled, injection-type vaporizer that is used exclusively with Maquet FLOW-i anesthesia workstations. Because these vaporizers are located upstream from the patient's breathing circuit, they are designated as out-of-circuit vaporizers, similar to the desflurane vaporizers and most variable bypass vaporizers. The Maquet injection vaporizers are agent-specific and available for isoflurane, sevoflurane, and desflurane. Externally, the device has a lid, filling port, electronic level indicator, and alert indicators, but no concentration control dial. Vaporizer output adjustments are accomplished through an electronic interface on the workstation.

The Maquet vaporizer principle of operation is illustrated in Fig. 22.28. Gas from the anesthesia machine enters through the drive gas inlet and pressurizes a reservoir of liquid anesthetic. This pressure provides the force to drive

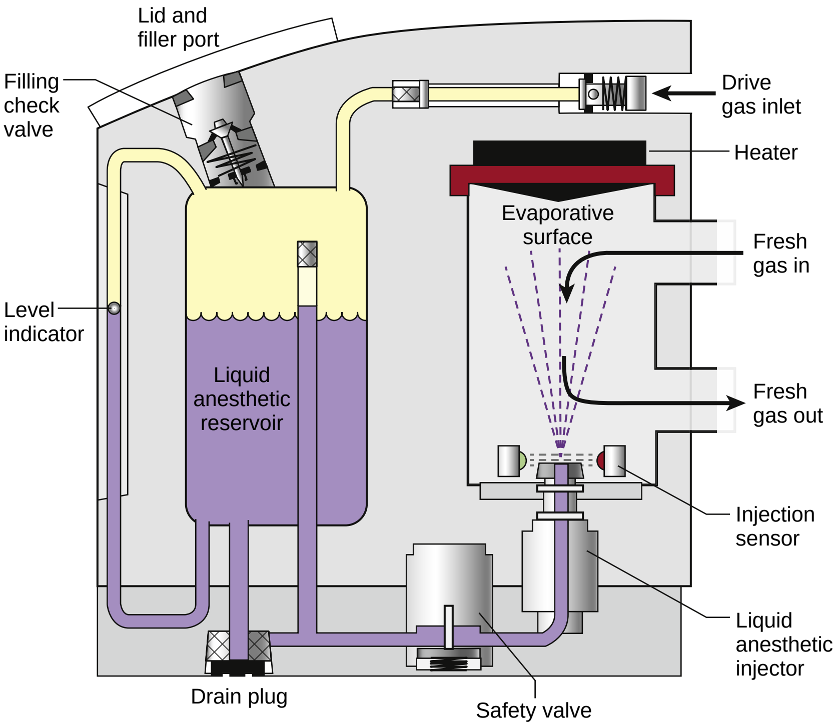

Fig. 22.28 The Maquet anesthetic vaporizer. Drive gas from the anesthesia machine is used to pressurize a liquid anesthetic reservoir. Under microprocessor control, liquid agent is injected into a vaporizing chamber. Injection is carefully monitored. A heated surface within the vaporizing chamber facilitates evaporation of the anesthetic agent. Fresh gas flows through the chamber and is enriched with anesthetic gas. A safety valve stops the flow of liquid agent in the case of vaporizer malfunction. (Personal communication, illustration adapted with permission from Maquet Critical Care, Solna, Sweden, January 14, 2013.)

liquid through the injector (and also minimizes evaporation within the reservoir chamber). Liquid anesthetic is injected into a heated vaporizing chamber in pulses that are under microprocessor control. Rapid evaporation occurs. Injection continues in small increments until the desired volume is obtained. The total amount injected in any given interval is based on the desired anesthetic concentration and the fresh gas flow through the vaporizer. A dedicated gas analysis line downstream from the vaporizer monitors the output. An optical sensor in the vaporizer monitors the integrity of the anesthetic injections (personal communication, Maquet Critical Care, January 14, 2013).

Fresh gas from the anesthesia workstation flows through the vaporizing chamber and is enriched with anesthetic agent. Although some of the injected liquid anesthetic evaporates while in flight within the vaporizing chamber, the remainder is deposited on a heated surface that ensures immediate evaporation. Heating of the evaporative surface is carefully regulated to compensate for evaporative cooling (personal communication, Maquet Critical Care, January 14, 2013).

During the daily workstation pre-use check, Maquet vaporizers are automatically tested with respect to functionality and leaks. A safety valve stops the flow of liquid agent in the event of vaporizer malfunction. The vaporizer is not vulnerable to tipping because it has no wicks to saturate, and agent cannot spill into the vaporizing chamber. The vaporizer can be filled during use, although no vaporizer output occurs during filling. An alarm triggers when the liquid anesthetic level is less than 10%, and a higher-priority alarm triggers when it reaches 5%. Limited data is available on the Maquet vaporizer's performance with different fresh gas flow rates,[121b] but the impact of changing barometric pressure, temperature, and fresh gas composition has not been reported.

Some Dräger anesthesia workstations are also equipped with vaporizers that function by the direct injection of volatile anesthetic (DIVA) principle (Fig. 22.29). Dräger DIVA vaporizers are agent specific. They consist of an interchangeable vaporizing module and a gas supply arrangement that is part of the workstation.[69a,121c] Liquid anesthetic agent is held in a reservoir. The liquid flows by gravity into a dosing chamber, where it is pressurized by gas supply from the workstation. The liquid passes through a dosing valve, and it is sprayed by a fuel injector into a heated vaporizing chamber. The anesthetic agent evaporates rapidly to its vapor pressure and is then conducted into the patient's breathing circuit under microprocessor control. The feedback control unit may be set to target a certain volatile agent concentration as a percentage of either the fresh gas stream or the patient's end-tidal gas.

Draw-Over Vaporizers in Contemporary Practice. As described above, most modern anesthesia workstations incorporate *plenum-type variable-bypass* vaporizers or other sophisticated units that require pressurized flow of carrier gases to drive vaporization and delivery. However, compressed medical gases (oxygen or air) are not available in many resource-constrained environments. *Draw-over* vaporizers remain a popular option for delivering anesthesia in such settings, including military field operations.[121d] They are characterized by (1) *in-circuit* location, (2)

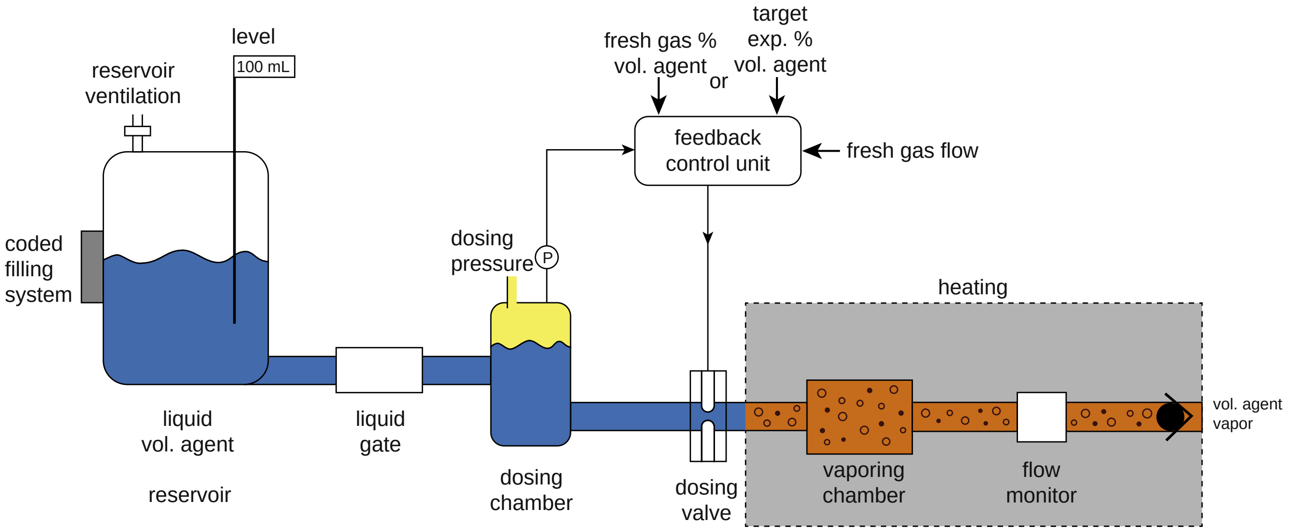

Fig. 22.29 Schematic of the Dräger DIVA vaporizer (Drägerwerk AG & Co. KGaA. Diagram reprinted with permission). The vaporizer consists of two modules: an interchangeable vaporizing module, and a gas supply module that is part of the anesthesia workstation. The vaporizing module includes a reservoir for liquid agent and a dosing chamber. The gas supply module consists of a feedback control unit that provides dosing pressure and control, as well as a system of valves. The valves may target vapor injection into either a mixing chamber (to mix with fresh gas flow) or directly into the breathing system (injection independent of fresh gas flow). See text for details.

low-resistance to gas flow, and (3) gas flow that is driven by negative downstream pressure (typically arising from the patient's respiratory effort, but potentially from a bellows or compressible bag). For a more thorough discussion of *draw-over* anesthesia technique in resource-limited settings, please see Chapter 2, Section 3. The basic design principles are worth a brief illustration.

The Oxford Miniature Vaporizer (OMV) is a stainless steel, variable-bypass, draw-over vaporizer that has been in use since 1968 and is particularly popular in the British Armed Forces.[121e] It has a robust, simple, and portable design and holds up to 50 mL of liquid anesthetic.[69b] A calibrated dial controls flow through an aperture between a slide valve and obturator located in the bypass chamber (Fig. 22.30).[121f] Closing the aperture directs more flow into the vaporizing chamber and increases output. Metal mesh wicks increase the surface area for vaporization yet add little resistance to gas flow. The OMV is not temperature compensated and output varies significantly with ambient temperature.[121g] It does feature a heat sink of water and ethylene glycol ("antifreeze") housed in the base to resist temperature swings. The OMV is not agent-specific, and different calibrated dials are available for halothane, isoflurane, and sevoflurane.[44] In order to deliver sufficient sevoflurane concentration for an inhaled induction, two OMVs must be used in series.[121h] Recently, the *Diamedica Draw-Over Vaporizer* (*DDV*) has been developed. Although similar in design to the OMV, the DDV tends to deliver more accurate results across a range of dial settings and ambient temperatures.[69a] It also has a larger reservoir (150 mL) for liquid agent and is available in two versions (halothane/isoflurane and sevoflurane).[121i]

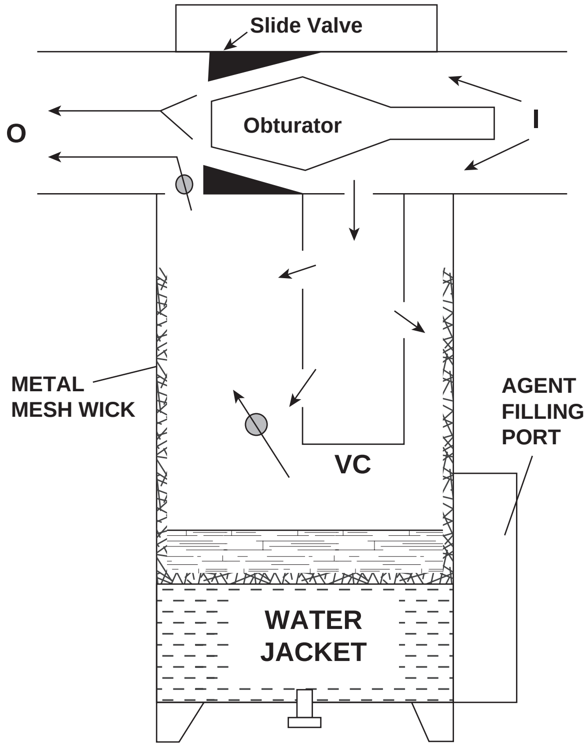

Fig. 22.30 **Oxford miniature vaporizer.** Gas flows from the inlet, *I*, through a slide valve and towards the outlet, *O*. A dial controls motion of an obturator that diverts flow to the vaporizing chamber, *VC*, and determines vaporizer output. (Redrawn from Dhulkhed V, Shetti A, Naik S, et al. Vapourisers: physical principles and classification. *Ind J Anaesth*. 2013;57[5]:455–419.)

Volatile Anesthetic Reflectors: AnaConDa and Similar Devices. There has been a resurgence of interest in providing inhaled volatile anesthetics to patients in locations outside of the operating room, such as the ICU, where commercial anesthesia workstations are not readily available.[121j] Indications for ICU delivery of volatile anesthetics include refractory bronchospasm and status epilepticus (see also Chapter 79), as well as a potential alternative to intravenous sedation.[121k] Barriers to providing volatile anesthesia in the intensive care setting include (1) rapid

consumption of volatile anesthetics due to the high gas flow rates of modern ICU ventilators, and (2) environmental safety and occupational health hazards due to atmospheric contamination and ineffective scavenging of waste gases.

One possible solution for ICU delivery of volatile anesthetics are *reflector*-style devices such as the *anesthetic conserving device* (AnaConDa) and *Mirus* device.[121l,121m] The AnaConDa is a single-use device based on a heat and moisture exchanger (HME) filter and does not require a power source or an anesthesia workstation (Fig. 22.31).[121n] Liquid volatile anesthetic (either isoflurane or sevoflurane) is injected into the device using a standard syringe pump and vaporized through a porous evaporator rod. The patient breathes in the anesthetic vapor normally. Upon exhalation, the breathing gases pass through several layers of filter. The first is an antimicrobial layer typical of HME filters. The second layer is activated carbon that rapidly adsorbs exhaled volatile anesthetic with high efficiency, while CO_2 and other exhaled gases pass through. Upon the next inspiratory cycle, the adsorbed volatile anesthetic molecules are released from the carbon filter and "reflected" towards the patient for re-breathing. The efficiency of the device is approximately 90%, with only 10% loss of vapor passing through the reflector to the ventilator waste gases. A gas sampling port allows for monitoring of end-tidal volatile agent concentration and titration of the syringe pump infusion rate. The Mirus device works on a similar concept, but is capable of delivering desflurane, and incorporates automatic control of end-tidal concentrations.[121l]

ANESTHETIC BREATHING CIRCUITS

Fresh gas departs from the supply system and enters the anesthetic breathing circuit through the fresh gas line. The functions of the breathing circuit are to deliver oxygen and other gases to the patient and to eliminate CO_2. The breathing system must contain a low-resistance conduit for gas flow, a reservoir that can meet the patient's inspiratory flow demand, and an expiratory port or valve to vent excess gas.[122] Beyond these fundamentals, circuits are categorized as those that use an absorber to eliminate CO_2 (the circle system) and those that do not (the Mapleson circuits).[123] Circle systems are the most common breathing circuits used for anesthetic delivery. However, certain Mapleson systems are used in anesthesia workstations, particularly in pediatrics, and they are often used by anesthesia providers during transport of patients, procedural sedation, liberation from tracheal intubation (the T-piece), and preoxygenation during out-of-the-operating-room airway management. Therefore both systems are discussed.

Leaks and obstruction represent the two most important hazards associated with the breathing circuit. Most of the time, these problems can be detected during the pre-use checkout of the workstation. However, a firm understanding of the components and function of the breathing system is critical if one is to perform a proper checkout and troubleshoot acute problems. The operator should also be aware of the various standards and alarms associated with this critical part of the anesthesia workstation.

Circle Breathing Systems

The circle breathing system is so named because it allows circular, unidirectional flow of gas facilitated by one-way valves. For many years, the overall design of the classic circle system changed little. Most anesthesia workstations had circle systems with similar schematics and components (Figs. 22.32–22.34). More recently, however, circle breathing systems have evolved along with the technological complexity of workstations. These changes have resulted from efforts to improve patient safety with features such as integrated fresh gas decoupling during positive-pressure ventilation.

The circle system consists of several essential components, including (1) a fresh gas inflow source, (2) inspiratory and expiratory unidirectional valves, (3) inspiratory and expiratory corrugated tubes, (4) a Y-piece that connects to the patient, (5) an overflow or APL or "pop-off" valve, (6) a reservoir or breathing bag, and (7) a canister containing a CO_2 absorbent (see Fig. 22.32). Several additional components are added to enhance patient safety, including a circuit pressure sensor, a pressure gauge, an expiratory (and possibly an inspiratory) flow sensor, and an inspired oxygen concentration sensor. A separate positive end-expiratory pressure (PEEP) valve may be present. Circle

Fig. 22.33 Spontaneous breathing: early expiratory phase. The inspiratory unidirectional valve ensures that all exhaled carbon dioxide (CO_2)–containing gas flows toward the breathing bag and adjustable pressure-limiting *(APL)* valve before being scrubbed of CO_2. Fresh gas continues to flow, but now in retrograde fashion, and combines with the exhaled breath. The APL valve remains closed in this example because circuit pressure is still lower than the practitioner-set APL valve pressure threshold (i.e., 10 cm H_2O). *PEEP,* Positive end-expiratory pressure. (Courtesy Dr. Michael A. Olympio; modified with his permission.)

systems must allow for spontaneous ventilation, manual ventilation, and positive-pressure mechanical ventilation, and therefore must function with both the anesthesia reservoir bag and ventilator. The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine.

Some of the main advantages of the circle system include (1) maintenance of relatively stable inspired gas concentrations; (2) conservation of respiratory heat and moisture, and anesthetic gases; (3) elimination of CO_2; and (4) prevention of operating room pollution. The capability to rebreathe exhaled gases is a unique aspect of circle systems as compared with ICU ventilators. Carbon dioxide is efficiently removed to allow safe rebreathing of exhaled gases. Waste gas, which is composed of excess carrier gas, anesthetic agent, and CO_2, is scavenged and eliminated.

Circle breathing systems have several disadvantages. First, they have a complex design that may consist of ten or more individual connections. These multiple links set the stage for misconnections, disconnections, obstructions, and leaks. In a closed-claim analysis of adverse anesthetic outcomes arising from gas delivery equipment, 39% of malpractice claims resulted from breathing circuit misconnections or disconnection.[124] Malfunction of unidirectional valves can be life-threatening. The circle breathing system is large and compliant when compared with the Mapleson systems, and this property may compromise tidal volume

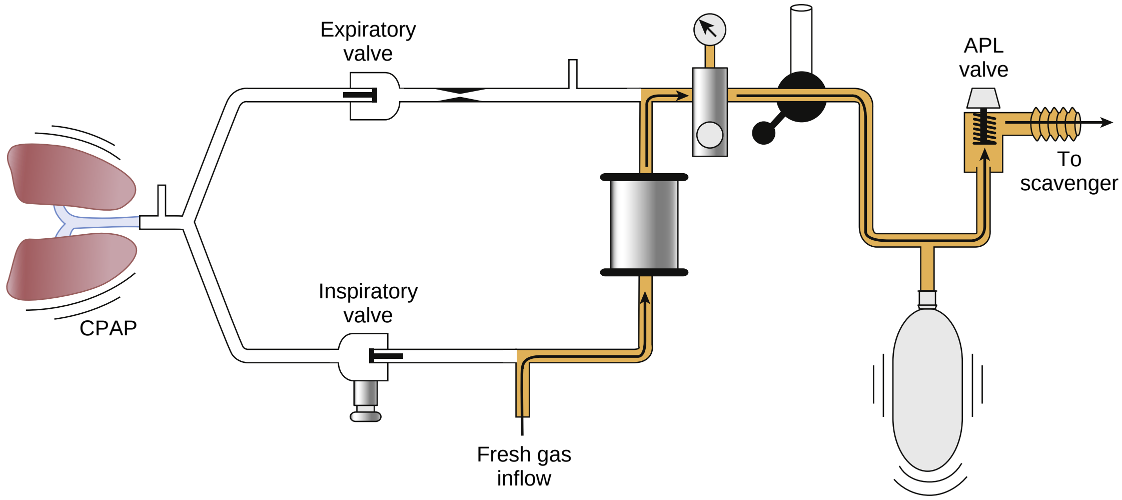

Fig. 22.34 Spontaneous breathing: end-expiratory phase with continuous positive airway pressure *(CPAP)*. Fresh gas continues to flow into the circuit generating pressure that maintains distention of the lungs (CPAP) and the breathing bag. Once the circuit pressure exceeds the adjustable pressure-limiting *(APL)* valve's set threshold (i.e., 10 cm H_2O), the valve opens, and excess gas flow is vented to the scavenger. (Courtesy Dr. Michael A. Olympio; modified with his permission.)

delivery during controlled ventilation. Finally, because circle breathing systems use a CO_2 absorber, anesthetic degradation can occur (see section on Carbon Dioxide Absorbers).[125] Specific perils associated with each component of the circle system are discussed in detail in the sections to follow.

Mechanical Components of the Circle Breathing System

Unidirectional Valves. The one-way valves are essential elements of the circle breathing system (Fig. 22.35). They are constructed to resist the humidity that sometimes accumulates in the breathing system. However, these usually reliable valves can occasionally fail during use. The expiratory valve seems to be more vulnerable because it is subject to greater moisture exposure. If a unidirectional valve sticks in the open position, inappropriate rebreathing of CO_2 may occur.[125a] Capnography may help with diagnosis, as each valve demonstrates a characteristic CO_2 waveform when incompetent.[126,126a] If the valves are stuck shut, total occlusion of the circuit can result. An expiratory valve stuck in the closed position can lead to barotrauma. Assessing for proper unidirectional valve function should be part of the anesthesia workstation pre-use check out procedure. Anesthesia machines are constructed so that valve function and motion can either be visibly assessed, or malfunction is indicated by the workstation.[11]

Adjustable Pressure-Limiting Valve. The APL valve is an operator-adjustable relief valve that vents excess breathing circuit gas to the scavenging system and provides control of the breathing system pressure during spontaneous and manual modes of ventilation. Switching the workstation to a ventilator mode excludes or closes the valve.[127] Several other common names exist for these devices, including "pop-off" valve and pressure relief valve.[122] The two basic types of APL valves are the variable-orifice (or variable-resistor) type and the pressure-regulating type. The variable-orifice type functions as a needle valve, much like a flow control valve (Fig. 22.36). The operator adjusts the outlet orifice size, so the resultant breathing system pressure at any given adjustment is directly related to the fresh gas flow rate. Modern machines now mostly use pressure-regulating type APL valves (Fig. 22.37). This type of APL valve has an adjustable internal spring and an external scale indicating the approximate opening pressure. When the pressure in the system exceeds spring tension, a disk opens and gas is vented (see Fig. 22.37*B*). Waste gas is prevented from returning from the scavenging system by a downstream check valve. By adjusting spring tension, the operator can choose the desired maximal circuit pressure in manual mode.[38,122] Unlike variable-orifice type valves, the pressure-regulating APL valves are designed to maintain stable circuit pressure even as fresh gas flow is increased. This type of valve usually has a fully open (to atmosphere) position for spontaneous breathing (see Fig. 22.37*C*). Continuous positive airway pressure (CPAP) can be more reliably controlled using this type of APL valve.

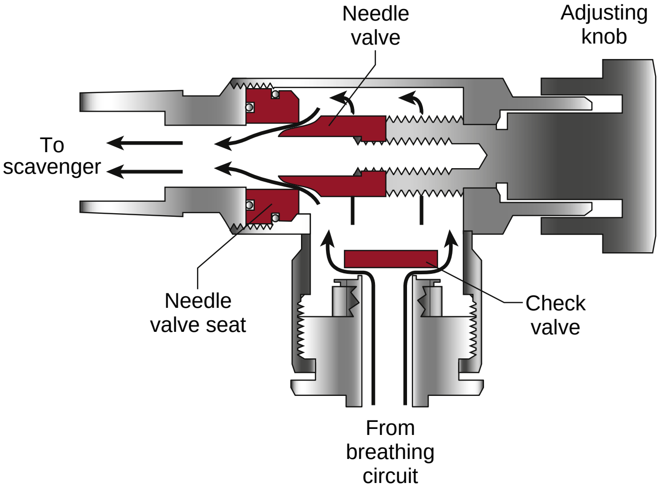

Fig. 22.36 Adjustable pressure-limiting valve: variable orifice type. A weighted check valve prevents gas from flowing backward after being sent to the scavenger. A variable orifice needle valve controls rate of gas egress from the breathing circuit, thereby controlling the circuit pressure. At any given adjusted valve orifice, the pressure in the circuit will depend on the fresh gas flow rate. (Modified from Yoder M. Absorbers and breathing systems. In: *Understanding Modern Anesthesia Systems*. Telford, PA: Dräger Medical; 2009:83–126.)

While APL valves are designed as a safety feature to allow precise control of circuit pressures during manual ventilation, problems do occur. A comparison of two modern anesthesia machines demonstrated that not all APL valves have equivalent linear behavior, and with certain valves the PIPs may routinely exceed set values.[127a] This serves as a reminder that the operator must vigilantly monitor circuit pressure during manual ventilation. Mechanical failures of APL valves have been reported due to breakage or trapping of gas sampling lines under the edge of the control knob.[127b,127c]

Anesthesia Reservoir Bag or "Breathing Bag." The anesthesia reservoir bag, or "breathing bag," provides several important functions, including (1) serving as a reservoir for exhaled gas and excess fresh gas, (2) providing a means of delivering manual ventilation or assisting spontaneous breathing, (3) serving as a visual or tactile means of monitoring a patient's spontaneous breathing efforts, and (4) partially protecting the patient from excessive positive pressure in the breathing system, such as in the case of inadvertent closure of the APL valve or an obstruction of the scavenge line [Fig. 22.38*A*]). Standard adult breathing bags have a nominal volume of 3 L; pediatric bags are available as small as 0.5 L. The reservoir bag is the most compliant part of the breathing system. The pressure-volume characteristics of standard bags are such that they inflate to a maximal pressure, and then slightly decrease to a plateau as filling continues to higher volumes (Fig. 22.38*B*).[122,128,129,129a] Anesthesia reservoir bags must adhere to pressure standards, which mandate a minimum pressure of approximately 30 cm H_2O and a maximum pressure of approximately 60 cm H_2O when the bag is filled to four times its stated capacity.[130] Although most bags adhere to these standards, some latex-free bags have exceeded the upper pressure limit.[129] Classically, the reservoir bag was excluded from the breathing circuit when the ventilator was in use. However, on most contemporary Dräger workstations,

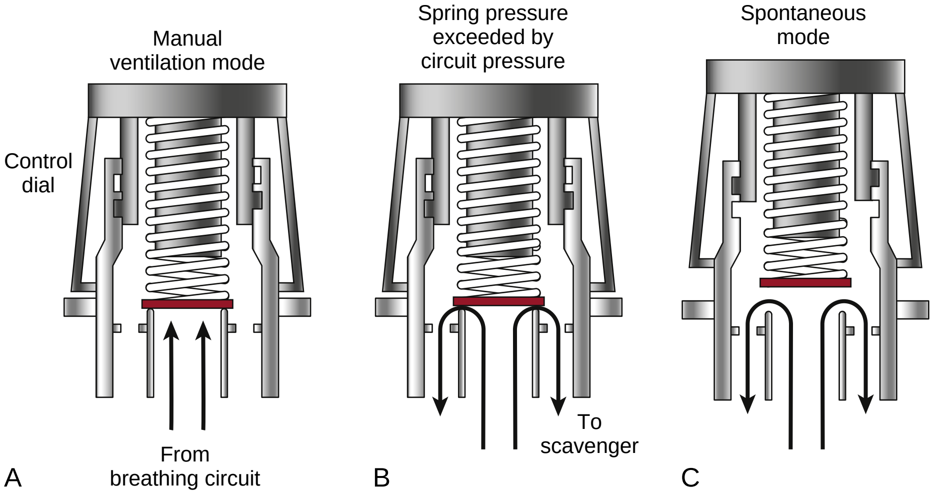

Fig. 22.37 Adjustable pressure-limiting valve: pressure-regulating type. (A) In the "manual" setting, the operator adjusts spring tension, thereby adjusting valve opening pressure. In this image the breathing circuit pressure has not yet exceeded spring tension. (B) Breathing circuit pressure has exceeded the set pressure (spring tension), and gas is vented to the scavenger. With the pressure regulating type of adjustable pressure-limiting valve, circuit pressure is independent of the fresh gas flow rate. (C) When the valve is placed in the spontaneous mode, the disk is lifted off the valve seat, and gas flows freely to the scavenger. A check valve downstream prevents waste gas from returning to the breathing circuit.

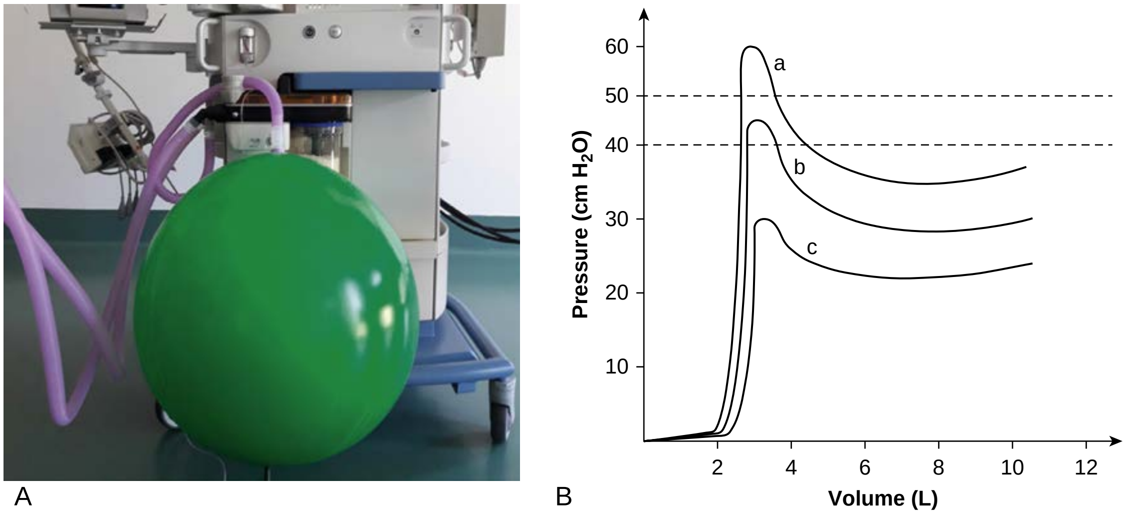

Fig. 22.38 Safety function of the breathing circuit reservoir bag when overdistended. The standard for reservoir bags is that the maximum pressure should not exceed approximately 60 cm H_2O at four times the stated capacity.[130] However, the pressure inside many reservoir bags peaks at a lower volume, and all should maintain a plateau pressure with further expansion.[128] (A) A breathing bag distended to a diameter of ~66 cm and volume of ~150 L. The pressure inside the bag is 34 cm H_2O. (B) Pressure versus volume filling curves for three different reservoir bags demonstrating a peak and plateau pressure. Vigilance should prevent overfilling from occurring because the continuing positive pressure alarm should be sounding while the bag is inflating. (From Križmarić M. Functions of anesthesia reservoir bag in a breathing system. *Slov Med J*. 2017;86:226–235.)

the reservoir bag is integral to circuit function during mechanical ventilation, where it serves as an exhaled and fresh gas reservoir.[31b,38,131,131a]

Corrugated Breathing Circuit Tubing. The breathing circuit tubing, which accounts for most of the volume within the circle system, has certain vulnerabilities. First, these circuits are compliant, and some of the volume intended for delivery to the patient during positive-pressure ventilation is lost to distention of the tubing. Many modern anesthesia workstations perform a compliance test to compensate for this effect. Alternatively, the workstation may compensate for discrepancies in the set versus delivered tidal volume. It is important that these tests be performed with the actual circuit that is to be used for anesthesia delivery. For instance, if a circuit extension is to be used to facilitate turning the operating room table 180 degrees, the compliance, leak, and flow tests should be performed with the extension in place. Circuit tubing may also be a source of leaks or obstruction (see below).

Y-Piece. The Y-piece is the distal (nearest the patient) part of the circuit that merges the inspiratory and expiratory limbs. It has a 15-mm inner diameter to connect to an endotracheal tube or elbow connector, and a 22-mm outer diameter to connect to a face mask. The dead space in the circle breathing system begins at the Y-piece and continues to the patient (i.e., the portions of the circuit with bidirectional gas flow, compare Figs. 22.32 and 22.33).[131b] On modern anesthesia machines, the gas sampling port is located at or near the Y-piece to allow monitoring of both inspiratory and expiratory gases.

Filters and Heat and Moisture Exchangers. The use of HMEs and filters within the anesthesia breathing circuit is common. HMEs help replace the normal warming and humidifying function of the upper airway, which is often bypassed by an artificial airway during anesthesia.[132] Filters are used to prevent the transmission of microbes from the patient to the machine and hence potentially to other patients. No consensus agreement pertaining to their use exists. Current ASA recommendations endorse the use of filters only in the context of patients with tuberculosis.[133] If a filter is to be used for this purpose, it should have an efficiency rating higher than 95% for particle sizes larger than 0.3 μm. The filter should be placed between the endotracheal tube and the Y-piece.[134]

Sensors

Inspired Oxygen Concentration Monitor. The ASTM standards state that the workstation must be equipped with a sensor to monitor the oxygen concentration in the inspiratory limb or at the Y-piece of the breathing circuit. A low oxygen concentration alarm must sound within 30 seconds if the fraction of inspired oxygen (FiO_2) drops below a set limit, which cannot be adjustable to less than 18% *v*/*v*%.[20] The oxygen sensor is truly the patient's last line of defense from receiving a hypoxemic gas mixture. *Galvanic cell oxygen analyzers* are often used for this purpose, but they have a finite life span and are prone to drift.[134a] They therefore require daily calibration during the workstation pre-use check. A common location for galvanic sensors is in the housing of the inspiratory unidirectional valve (see Fig. 22.32). Modern anesthesia workstations (e.g., Dräger Apollo) increasingly use *side-stream multigas analyzers at the Y-piece* as the exclusive inspiratory oxygen monitor.[131a,134c] *Paramagnetic oxygen analyzers*, which require less frequent calibration, are typically used in these monitors.

Flow Sensors. Flow sensors are used on the anesthesia machine primarily to measure tidal volume. The workstation must have a device that monitors the patient's exhaled tidal volume, minute ventilation, or both.[11] These sensors may also be used to display flow waveforms and/or flow-volume loops. Finally, some workstations use flow sensor measurements as a feedback signal to maintain stable tidal volume delivery at varying fresh gas flow rates. Although early flow sensors were usually mechanical respirometers, contemporary machines may use differential pressure sensors, heated-wire anemometers, ultrasonic flow sensors, or variable-orifice flow sensors. The location of the flow sensor can vary, but a sensor for exhaled gas flow is required at a minimum.

Breathing Circuit Pressure Sensors. The continuous measurement of airway pressure in the breathing circuit is critical to patient safety. Several requirements must be met. First, anesthesia workstations must continuously display pressure in the breathing system. Second, operator-adjustable alarms must be present for *high pressure* as well as for *continuous positive pressure* lasting 15 seconds or longer. Excessive high pressure or prolonged positive airway pressure can compromise venous return, decrease cardiac output, interfere with ventilation, or cause barotrauma. An alarm must also sound if *negative pressure below* -10 *cm* H_2O occurs in the breathing circuit for more than 1 second. Finally, when automatic ventilation is in use, the machine must alarm whenever the breathing pressure falls below a preset or adjustable *threshold pressure* for more than 20 seconds. This alarm may serve as a disconnection alarm, but low-volume or exhaled CO_2 monitoring may also be used (see below).[11] The location of pressure sensors in the breathing system varies. They are often located in the nondisposable portion of either the inspiratory or expiratory limb near one of the unidirectional valves.[134b] Dräger machines transduce pressure from the CO_2 absorber system.[131a] It is important to remember that the breathing circuit pressure may not accurately represent the patient's airway pressure, especially if the pressure sensor is located far from the Y-piece.[134b] Older machines have a mechanical pressure gauge, while newer models may display a digital representation of this gauge.

Circle System Function—Semiclosed, Semiopen, and Closed Systems. Circle system function is illustrated in Figs. 22.32–22.34. The extent of rebreathing, and therefore the conservation of exhaled gases, depends on the fresh gas flow rate. Higher fresh gas flow rates result in less rebreathing and greater waste gas. Contemporary circle systems are usually operated in a *semiclosed* manner, meaning that some rebreathing occurs, but some waste flow is vented through the APL or waste gas valve of the ventilator. The delivery of *low-flow* anesthesia (≤1.0 L/min fresh gas flow) with a circle system exemplifies a *semiclosed* system. *Low-flow* anesthesia generally refers to a technique where fresh gas flow is less than minute ventilation, and at least 50% of expired gas is rebreathed after carbon dioxide removal.[131b]

A circle system operated in a *semiopen* manner implies a higher fresh gas flow rate with minimal rebreathing and more venting of waste gas. The advantages of conducting *low-flow* or *minimal-flow* (≤0.5 L/min) anesthesia include the decreased use of volatile anesthetic agents, improved temperature and humidity control, and reduced environmental pollution. The disadvantages include difficulty in rapidly adjusting anesthetic depth and the theoretical possibility of accumulating unwanted exhaled gases (e.g., carbon monoxide, acetone, methane) or volatile anesthetic degradation products (e.g., compound A, carbon monoxide—see section on carbon dioxide absorbers later).[135]

A *closed* system is one in which the rate of oxygen inflow exactly matches metabolic demand, rebreathing is complete, and no waste gas is vented. A volatile anesthetic agent is added to the breathing circuit in liquid form in precise amounts or is initially introduced through the vaporizer.[136] Closed-circuit anesthesia maximizes the advantages of *low-* and *minimal-flow* anesthesia. However, the vigilance demanded by this technique make it impractical for routine use with contemporary equipment; thus it is rarely employed.[137]

Potential Circle System Problems

LEAKS AND DISCONNECTIONS. Breathing circuit leaks and disconnections continue to cause critical incidents in anesthesia.[140] Common sources of leaks include disposable tubing and components, as well as points of connection within the breathing circuit and at the CO_2 absorber canister.[141] Although leaks can develop during the course of anesthesia, such as a partial disconnection, most can be detected during a thorough workstation pre-use checkout. Leaks can be small, and easily overcome by increasing fresh gas flow to compensate for lost volume, or they can be very large and render ventilation impossible. No matter the size, *all leaks should be investigated*. Several monitors can assist the anesthesia provider in detecting a leak or circuit disconnection during the course of anesthetic care (Table 22.7).

Breathing circuit pressure monitoring is an extremely important aid in diagnosing leaks and disconnections. As discussed earlier, breathing circuit pressure monitoring is a required feature of anesthesia workstations. The *threshold pressure* (or *low peak inspiratory pressure*) alarm is useful for detecting leaks and disconnections. When using a controlled ventilation mode, an audible and visual alarm is generated if the breathing system pressure drops below the threshold limit for more than 20 seconds (Fig. 22.39*A*). Visual alarm examples include "Apnea Pressure," "Check Breathing Circuit," and "Low Pressure."[38,141a,141b] The specific times required before sounding the alarm may vary slightly between machines. The *threshold pressure alarm* limit is operator-adjustable on some machines, and may also have an "autoset" feature that applies an algorithm to set an appropriate limit based on current airway pressures.[131,141c] As can be seen in Fig. 22.39*B*, setting the threshold limit too low may allow a partial disconnection (leak) to go unrecognized. Conversely, setting the threshold limit too high can result in an erroneous alarm.

Respiratory volume monitors (flow sensors) are useful in detecting leaks or disconnections. Low exhaled tidal volume and/or low minute ventilation alarms may first alert the operator to these problems. The user should bracket the minute ventilation alarms slightly higher and lower than the patient's requirements. An autoset feature may be available for minute ventilation monitoring as well.[131] Some workstations will alarm if a significant disparity exists between inhaled and exhaled tidal volumes, or when the measured tidal volume does not achieve the set tidal volume.[142]

Finally, all modern workstations have integrated gas monitoring with alarms for *exhaled* CO_2. Total loss of the

TABLE 22.7 Methods of Detecting Leaks and Disconnections During the Course of Anesthesia

capnogram should alert the operator to a loss of ventilation and possible circuit disconnect. More subtle changes in capnogram amplitude or waveform may indicate a leak.

MISCONNECTIONS. Unfortunately, misconnections of the breathing system are not rare. Anesthesia workstations, breathing systems, ventilators, and scavenging systems incorporate many diameter-specific connections. Despite the efforts of standards committees to assign different diameters to various circuit connections, misconnections continue to occur. The ingenuity of some individuals in outwitting these "foolproof" systems has led to various hoses being adapted or forcefully fitted to inappropriate terminals, and even to various other solid cylindrical protrusions of the anesthesia machine.[143,144] Operators and technicians should be properly trained on their respective workstations and modifications should be discouraged.

OBSTRUCTION. Occlusion (obstruction) of the breathing circuit may occur and can have severe consequences. Tracheal tubes may kink. Breathing circuit valves or other components can malfunction. Hoses throughout the breathing circuit are subject to occlusion by internal obstruction or external mechanical forces that can impinge on flow. Blockage of HMEs by secretions can also cause significant obstruction.[145] Case reports describe bilateral tension pneumothorax caused by blockage of a bacterial filter in the expiratory limb,[146] or a misplaced disk in an expiratory valve.[147] Because retained CO_2 absorber canister wrappings have caused circuit obstruction, ASTM standards now require that absorbers be packaged in a way that immediately identifies the presence of a wrapper.[127,148,149] Defects associated with disposable circuit components or the tubing itself have caused severe circuit obstruction and sometimes injury to the patient.[150-154] Misplaced Luer caps have made their way into the elbow connector of the circuit because of packaging or processing and have caused obstruction.[155,156] Incorrect insertion of flow direction-sensitive components

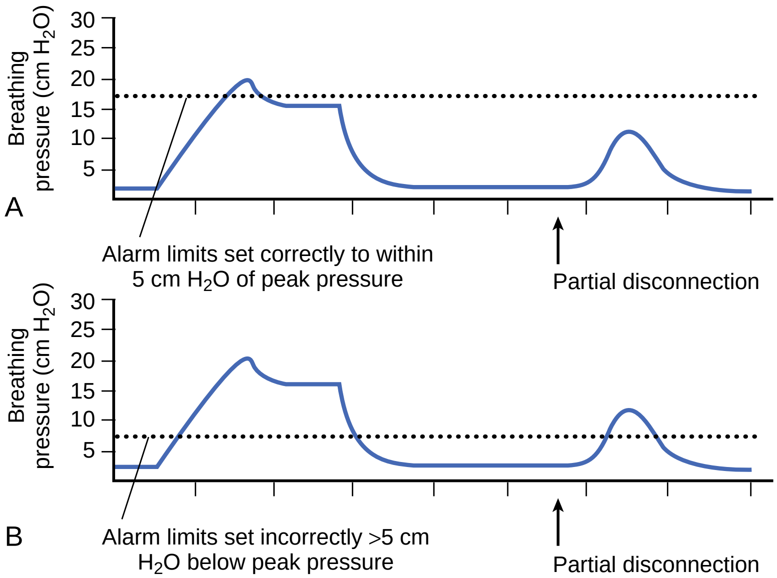

Fig. 22.39 Threshold pressure alarm limit. (A) The threshold pressure alarm limit *(dotted line)* has been set appropriately. An alarm is actuated when partial disconnection occurs *(arrow)* because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. (B) Partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has been set too low. (Redrawn from North American Dräger. *Baromed Breathing Pressure Monitor: Operator's Instruction Manual.* Telford, PA: North American Dräger; 1986.)

can result in a no-flow state. Examples of these components include some older PEEP valves and cascade humidifiers. Only the performance of a manual circuit flow test, or a similar automated test, during the pre-use checkout will reliably detect an obstruction. *If you are struggling to ventilate a patient and are unsure why, do not delay in switching to a self-inflating resuscitation bag.* Ventilate the patient first, troubleshoot later.

Variations in Circle Breathing System Design. Numerous variations of the circle system are possible, depending on the relative positions of the unidirectional valves, the APL valve, the reservoir bag, the CO_2 absorber, and the site of fresh gas entry. However, to prevent rebreathing of CO_2 in a traditional circle system, three rules must be followed: (1) a unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs, (2) the fresh gas inflow cannot enter the circuit between the expiratory valve and the patient, and (3) the APL valve cannot be located between the patient and the inspiratory valve. If these rules are followed, any arrangement of the other components will prevent rebreathing of CO_2.[125] Design departures from the traditional circle breathing system are becoming more common as workstations evolve. Some of these designs are driven by strategies to eliminate the impact of varying fresh gas flow rates or oxygen flush on inspiratory tidal volume and airway pressure during mechanical ventilations (fresh gas decoupling or compensation). These variations are addressed later, in section on anesthesia ventilators.

Carbon Dioxide Absorbers

Circle breathing systems require a means of CO_2 removal from the exhaled gases to avoid rebreathing and hypercapnia. Although increasing the fresh gas inflow to high levels can dilute out most CO_2 in the circle system, this is a very inefficient way to conduct an anesthetic. Because typical gas flows through the anesthesia machine are less than minute ventilation (*semiclosed* system), absorption of CO_2 is essential. If one could design an ideal CO_2 absorbent, its characteristics would include a lack of reactivity with common anesthetics, an absence of toxicity, low resistance to airflow, minimal dust production, low cost, ease of handling, and high efficiency. It should also be easy to assess for absorbent depletion (i.e., a diminished ability to remove CO_2). Finally, the container that houses the absorbent should be easy to remove and replace, should maintain breathing circuit integrity if quickly replaced during use, and should impose minimal risk of causing breathing system leaks or obstruction. Carbon dioxide absorbers are not unique to anesthesiology. They are also used in certain military and commercial diving equipment, submarines, space operations, mining and rescue operations, and hyperbaric facilities. In these environments, CO_2 absorbers are often referred to as *CO_2 scrubbers*.

Absorber Canister. Although CO_2 absorber canister configurations vary, they must be visible to the operator and transparent to monitor for absorbent presence and color. On traditional anesthesia machines, the absorber consists of a single clear plastic canister (or two canisters arranged in series). Opening a traditional canister assembly abolishes the integrity of the breathing circuit. If the absorbent needs to be changed in the course of anesthesia, and apnea cannot be tolerated, it is necessary to ventilate by other means. These older canisters are a common source of leaks due to their multiple components and compression assembly method.[141] The canisters are filled either with loose bulk absorbent or with factory-supplied disposable cartridges called *prepacks*. Loose granules from bulk absorbent may lodge between the canister and the O-ring gasket of the absorber and create a clinically significant leak. Leaks have also been caused by defective prepacks or those that were larger than factory specifications.[154,157] Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed before use.[148] Problems with rebreathing CO_2 have been caused by canister apparatus reassembly issues.[158-160]

Many modern workstations now use single canister absorbers that are disposable and easily replaceable. Increasingly, workstation design allows the canister to be replaced during anesthesia without interfering with breathing system integrity, sometimes referred to as a *bypass* feature.[141a] A potential risk imposed by this feature is that the machine may pass an automated or manual leak test *without* the absorber attached.

Chemistry of Absorbents. Carbon dioxide is removed from the breathing circuit through absorption by chemicals within the absorber canister. Through a series of reactions, CO_2 is transformed into water, heat, and other byproducts through a chemical process that neutralizes an acid (CO_2 or carbonic acid) with one or more basic compounds. Most absorbents use calcium hydroxide [$Ca(OH)_2$] to react with the expired CO_2, producing insoluble calcium carbonate ($CaCO_3$) (Box 22.2). However, because CO_2 does not react quickly with $Ca(OH)_2$, water and small amounts of stronger base catalysts are required to speed up the reaction. Calcium hydroxide-based absorbents vary in content of water, strong base

BOX 22.2 Carbon Dioxide Absorber Reactions (Net and Sequential)

Carbon Dioxide Reaction With Soda Lime

Net Reaction

$$CO_2 + Ca(OH)_2 \rightarrow CaCO_3 + H_2O + \text{heat}$$

Sequential Reactions

1. $CO_{2\ (gas)} + H_2O_{\ (liquid)} \rightleftharpoons H_2CO_{3\ (aqueous)}$
2. $H_2CO_3 + 2NaOH \text{ (or KOH)} \rightarrow Na_2CO_3 \text{ (or } K_2CO_3) + 2H_2O + \text{heat}$
3. $Na_2CO_3 \text{ (or } K_2CO_3) + Ca(OH)_2 \rightarrow CaCO_3 + 2NaOH^* \text{ (or KOH}^*) + \text{heat}$

Carbon Dioxide Reaction With Lithium Hydroxide Monohydrate

$$2\ LiOH{\bullet}H_2O + CO_2 + \text{heat} \rightarrow Li_2CO_3 + 3H_2O$$

*Note: Sodium hydroxide (NaOH) and potassium hydroxide (KOH) are catalysts in this reaction mechanism (they are neither created nor destroyed). *LiOH*, Lithium hydroxide.

catalysts (e.g., sodium hydroxide or potassium hydroxide), humectants (e.g., calcium chloride), and hardening agents such as silica. Newer absorbents only have trace amounts of potassium hydroxide (KOH) or sodium hydroxide (NaOH) because these bases have been associated with anesthetic degradation. One absorbent brand replaces $Ca(OH)_2$ entirely with lithium hydroxide (LiOH), which does not require any additional catalysts to react with CO_2. Key differences in absorbents include their capacity for CO_2 and their propensity to react with volatile anesthetics and produce potentially harmful degradation products (e.g., carbon monoxide and compound A). The composition of several absorbents is shown in Table 22.8.[161-166]

Soda lime is a mixture of chemicals that contains about 80% $Ca(OH)_2$, also known as *slaked lime*, along with water and small amounts of strong base (see Box 22.2). First, CO_2 reacts with liquid water present on and within the absorbent granules to yield carbonic acid (H_2CO_3). This step requires water and explains why all $Ca(OH)_2$-based absorbents contain approximately 15% H_2O by mass. Second, the strong base additives NaOH and KOH react quickly with H_2CO_3 to yield the soluble salts sodium carbonate (Na_2CO_3) and potassium carbonate (K_2CO_3). All available active strong base is quickly depleted. Third, the carbonates react with $Ca(OH)_2$ to yield insoluble $CaCO_3$. Note that NaOH and KOH are regenerated in this step and therefore meet the definition of catalysts. Since additional CO_2 cannot dissolve in water until H_2CO_3 is consumed by strong base (step 2), the rate of NaOH and KOH regeneration (step 3) is the rate-limiting step.[166a] Some CO_2 may react directly with $Ca(OH)_2$, but as mentioned, this reaction is slower. Byproducts of the entire process are water and heat.[167,168]

Unlike soda lime and the $Ca(OH)_2$-based absorbents, LiOH-based absorbents do not require catalysts. LiOH is a strong base and reacts quickly with CO_2. Although liquid water is not required to generate carbonic acid as in the classic $Ca(OH)_2$ reaction, some water molecules are still required for the CO_2 reaction with LiOH. These water molecules are supplied by humidity in the exhaled breathing gases and combine with the crystal lattice of LiOH in a 1:1 ratio through a process called "hydration."[168a] LiOH that does not contain water is referred to as *lithium hydroxide anhydrous.* LiOH chemically bound to water is called *lithium hydroxide monohydrate* ($LiOH{\bullet}H_2O$). Because the hydration reaction is *exothermic* (gives off heat), absorbents composed of *LiOH anhydrous* generate heat as they extract humidity during use. *LiOH monohydrate*-based absorbents are hydrated at the factory and therefore generate less heat when used in circle breathing systems. Once hydrated, LiOH removes CO_2 from the breathing circuit through an endothermic reaction (absorbs heat) that produces insoluble lithium carbonate (see Box 22.2).

Interactions of Inhaled Anesthetics With Absorbents

FORMATION OF POTENTIALLY HARMFUL DEGRADATION PRODUCTS. Volatile anesthetic agents have long been known to interact with the strong bases (KOH and NaOH) found in $Ca(OH)_2$-based absorbents to form degradation products. For historical perspective, trichloroethylene, a volatile anesthetic introduced to clinical use in 1940, was found to be associated with neurologic toxicity (particularly cranial nerve neuropathies and encephalitis).[169,170] Experimental investigation determined that dichloroacetylene, a toxin, was being formed by a base-catalyzed reaction with prior formulations of soda lime. This reaction was more likely to occur if the soda lime had a high content of strong base and was dry. Today, the main degradation products of concern are compound A, associated with the use of sevoflurane, and carbon monoxide (CO), mainly associated with the use of desflurane, enflurane, and isoflurane.[171] Other degradation products include formaldehyde and methanol, but these are not discussed here.[165]

COMPOUND A PRODUCTION. Sevoflurane can undergo a base-catalyzed degradation into fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether, known as *compound A.* Compound A is nephrotoxic to rats at concentrations that can occur in the breathing circuit during clinical conditions.[169,172] Moreover, in a limited number of volunteer studies, sevoflurane was associated with transient albuminuria and glucosuria.[173,174] To date, however, mounting data show no relationship between sevoflurane use and postoperative renal dysfunction in humans (including patients with preoperative renal insufficiency).[169,175-180] The sevoflurane package insert states that patient exposure should not exceed 2 MAC-hours at flow rates between 1 and 2 L/min in order to minimize risk from compound A. Flow rates less than 1 L/min are not officially recommended, although these recommendations predate several studies demonstrating safety at lower flow rates.

Several physical factors may predispose to higher concentrations of compound A in the breathing circuit, including the following:

- Low-flow or closed-circuit anesthetic techniques
- Higher concentrations of sevoflurane
- Type of absorbent (KOH or NaOH-containing)
- Higher absorbent temperatures
- Fresh absorbent[171,172,175,181]

The type and ratio of strong bases within the CO_2 absorbent affects the degree of sevoflurane degradation. KOH seems to cause more breakdown than NaOH.[164,166] For example, classic soda lime and Baralyme (which was voluntarily withdrawn from the market) both contain significant amounts of KOH and have a greater propensity to generate compound A than newer absorbents (see Table 22.8).[166] LiOH-based absorbents and newer $Ca(OH)_2$-based absorbents that are free of KOH and NaOH generate zero or negligible amounts of compound A.[162,163,166,182,182a,182b] Given the safe track record of sevoflurane and ongoing improvements in CO_2 absorbents, it may be concluded that compound A poses minimal risk to patients during routine clinical practice.

CARBON MONOXIDE PRODUCTION. Strong-base containing absorbents that are extremely dry (desiccated) can also degrade inhaled anesthetics to clinically significant concentrations of CO.[164] Under certain conditions, this process can produce blood carboxyhemoglobin levels of 35% or greater in an exposed patient.[184] A typical scenario involving a dangerous CO exposure would be the first case on a Monday morning, after high continuous gas flows had accidentally been left on throughout the weekend and desiccated the absorbent.[185,186] Machines in remote locations are more frequently found with desiccated absorbent.[186] Prolonged fresh gas flow rates of 5 L/min or greater are sufficient to cause critical drying of the absorbent, especially when the breathing bag is left off the circle system. Because the inspiratory valve leaflet produces some resistance to flow, fresh gas tends to flow retrograde through the absorber and out the breathing bag mount (the path of least resistance). The presence of a breathing bag allows slight pressure build-up that resists this flow (see the classic circle breathing system in Fig. 22.32).[184] Desiccation of absorbent is unlikely to occur during anesthesia delivery since CO_2 absorption produces water (and patients exhale humidified gas).

Several factors increase the production of CO and risk of carboxyhemoglobinemia:

- Inhaled anesthetic used (for a given MAC multiple, the magnitude of carbon monoxide production is desflurane ≥ enflurane > isoflurane >> halothane = sevoflurane)
- Degree of desiccation of the absorbent
- Type of absorbent (KOH or NaOH-containing)
- Higher temperature
- Higher concentrations of anesthetic[187]
- Low fresh gas flow rates
- Smaller patient size[188,189]

As with compound A production, the presence of strong bases (KOH and NaOH) in the desiccated absorbent correlates with the propensity to degrade certain anesthetics and liberate CO. Therefore Baralyme (now withdrawn) and to a lesser extent soda lime were more likely to produce CO when desiccated than newer-generation absorbents (see Table 22.8).[190] Omission of NaOH and KOH from the $Ca(OH)_2$-based absorbents reduces or eliminates the potential to produce CO or compound A without significant impact on the capacity for CO_2 absorption.[182,191] LiOH absorbent produces essentially no CO and maintains excellent CO_2 absorption.[162,182b,191a]

ABSORBENT HEAT PRODUCTION. One extremely rare but potentially life-threatening complication related to CO_2 absorbent is the development of extreme exothermic reactions that lead to fires and explosions.[192-194] Specifically, this seems to occur when desiccated strong base absorbents (particularly Baralyme) interact with sevoflurane. Under experimental conditions, desiccated Baralyme absorbers exceeded 200°C (392°F) and higher, and fire was noted in some of the breathing circuits.[195] The buildup of very high temperatures, flammable degradation products (formaldehyde, methanol, and formic acid), and oxygen- or nitrous oxide-rich gases within the absorber provide all the ingredients necessary for combustion.[196] Avoiding the use of sevoflurane with strong base-rich absorbents (e.g., the now discontinued Baralyme), especially when desiccated, is the best way to prevent such complications. Anhydrous LiOH may also generate high temperatures by reacting with moisture from expired gas, but formulations of LiOH monohydrate do not.

A consensus statement established by the Anesthesia Patient Safety Foundation provides recommendations to reduce the risk of volatile anesthetic degradation by desiccated CO_2 absorbents[164]:

- Turn off all gas flow when the machine is not in use
- Change the absorbent regularly
- Change the absorbent if color change indicates exhaustion
- Change all absorbent (not just one canister in a two-canister system)
- Change the absorbent when uncertain about the state of hydration (e.g., if fresh gas flow is left on for an extensive or indeterminate period of time)
- If compact canisters are used, change them more frequently

Given the improvements in absorbent chemistry detailed above, it seems prudent to select an absorbent that minimizes risk of adverse reactions whenever possible. Finally, educating anesthesia personnel about these hazards and preventive measures may also reduce the likelihood of adverse events.

Indicators. Conventional absorbents contain an indicator dye, *ethyl violet*, that allows anesthesia personnel to visually assess the functional integrity of the absorbent. Ethyl violet is a substituted triphenylmethane dye that undergoes a color change around pH 10.3.[168] When the absorbent is fresh, the pH exceeds 10.3 and the dye is colorless. As the absorbent becomes exhausted, the pH drops below 10.3 and the dye becomes purple. The color change indicates that the absorptive capacity of the material has been depleted. Unfortunately, ethyl violet may not always be a reliable indicator. For example, prolonged exposure of ethyl violet to fluorescent light can photodeactivate the dye. When this occurs, the absorbent will remain white even when exhausted.[197] Similarly, color reversion (purple back to white) can occur with some absorbents due to the strongly alkaline nature of NaOH. Many newer indicators are resistant to color reversion, and several now endorse permanent color change. At least one absorbent contains no indicator and relies upon the detection of inspired CO_2 by the gas analyzer and/or a time schedule to trigger replacement.

Absorbent desiccation is impossible to detect by visual inspection. Therefore some newer generation $Ca(OH)_2$ absorbents also include desiccation indicators. Users should refer to the product manufacturer's literature to determine whether their absorbent uses this type of indicator.

Carbon Dioxide Removal Capacity and Absorber Resistance. The ability of the workstation's absorber to remove CO_2 is related to three main factors: (1) the amount of absorbent surface area exposed to the exhaled gas, (2) the intrinsic capacity of the absorbent to remove CO_2, and (3) the amount of nonexhausted absorbent remaining. The size and shape of the absorptive granules are intended to maximize surface area while minimizing resistance to airflow.[198] The smaller the granule size, the greater the surface area that is available for absorption. However, as particle size decreases, airflow resistance increases. The size and shape of the granules is proprietary, but most absorbents have a granule size between 4 and 8 mesh-a size at which surface area and resistance are optimized. (Mesh size refers to the number of openings per linear inch in a sieve through which the granular particles can pass. For example, a 4-mesh screen means that there are four quarter-inch openings per linear inch.[167]) The presence of excess liquid water within the canister can decrease the exposed granule surface area and therefore the efficiency of CO_2 absorption.

As the absorbent granules stack up in canisters, small passageways inevitably form. These passages allow gas to flow preferentially through low-resistance areas. This phenomenon, known as *channeling*, may substantially decrease the functional absorptive capacity.[199] Recently, a nongranular polymer matrix product was released that binds particles together in a solid sheet of absorbent that has molded airflow channels, eliminating the phenomenon of channeling (personal communication, Micropore, Inc., Elkton, MD, June 3, 2014).

If completely reacted, a pound of $Ca(OH)_2$ has the capacity to absorb 0.59 lb of CO_2. LiOH has a higher capacity of 0.91 lb of CO_2 per pound.[199a] Consequently, LiOH absorbents typically neutralize or "scrub" more CO_2 per unit weight (which is of great importance when planning submarine missions or space travel).[199a,199b]

Mapleson Breathing Systems

In 1954, Mapleson described and analyzed five different breathing circuits, designated A through E (Fig. 22.40).[200] In 1975, Willis and coauthors described the F system, which was added to the original five.[201] The Mapleson systems share certain features with the circle breathing system: they accept fresh gas flow, supply the patient with gas from a reservoir to meet inspiratory flow and volume requirements, and eliminate CO_2. They differ from the circle system by having bidirectional gas flow and lacking an absorber. To eliminate CO_2 and prevent rebreathing, these systems depend on a higher rate of fresh gas inflow. The Mapleson systems consist of several common components, including a connection point to a facemask or endotracheal tube, reservoir tubing, fresh gas inflow tubing, and an expiratory pop-off valve or port. All the circuits except for Mapleson E use a bag as an additional reservoir. The Mapleson A, B, and C systems are rarely used today, but the D, E, and F systems are commonly used. In the United States, the most popular representatives from the DEF group are the Bain circuit and the Jackson-Rees circuit.

Three distinct functional groups can be seen: A, BC, and DEF groups. The Mapleson A, also known as the "Magill circuit," has a spring-loaded pop-off valve located near the facemask. It is the only Mapleson circuit where fresh gas flow enters from the end of the circuit opposite the patient (in this case, near the reservoir bag). The Mapleson A is functionally quite different from the other circuits, and has drastically different performance when used for spontaneous versus controlled ventilation (see later). In the B and C systems, both the pop-off valve and fresh gas inlet tubing are located near the patient. The Mapleson C is known as the "Waters to-and-fro" circuit and lacks a corrugated tube. The reservoir tubing and breathing bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson D, E, and F, or "T-piece" group, fresh gas enters near the patient, and excess gas is vented off at the opposite end of the circuit. The Mapleson F circuit is known as the "Jackson-Rees" modification of the Mapleson E (also known as "Ayre's T-piece").

Even though the components and their arrangement are simple, functional analysis of the Mapleson systems is complex.[202,203] The amount of CO_2 rebreathing with each system is multifactorial and affected by: (1) the fresh gas inflow rate, (2) minute ventilation, (3) ventilation mode (spontaneous or controlled), (4) tidal volume, (5) respiratory rate, (6) the inspiratory-to-expiratory ratio, (7) the duration of the expiratory pause, (8) peak inspiratory flow rate, (9) the volume of reservoir tubing, (10) the volume of the breathing bag, (11) the airway device being used (mask or endotracheal tube), and (12) the CO_2 sampling site.

Analysis of Gas Flow in the Mapleson A System. The performance of the Mapleson systems is best understood by studying the expiratory phase of the respiratory cycle.[204] Illustrations of the gas distribution at end-expiration is shown for each system (see Fig. 22.40).[204,204a] Of all the circuits, only the Mapleson A has markedly different performance when used for spontaneous versus controlled ventilation. During spontaneous ventilation, exhaled alveolar gas is vented through the pop-off during the expiratory phase (Fig. 22.40*A*). With the next inspiration, the patient primarily draws in fresh gas (and a small amount of dead space gas). Thus the Mapleson A has the best efficiency of the six systems for spontaneous breathing. A fresh gas inflow rate of greater than or equal to minute ventilation is sufficient to prevent rebreathing of CO_2.[205]

However, the Mapleson A has the worst efficiency during controlled ventilation. As the reservoir bag is squeezed to initiate inspiration, exhaled alveolar gas first flows into the patient (Fig. 22.40*A*, *inset*). The pop-off valve then opens and vents significant amounts of the fresh gas stream away from the patient during the inspiratory phase.[204a,205a] Significant rebreathing of CO_2 occurs unless minute ventilation is very high (>20 L/min). The key factor determining Mapleson A performance is the timing when the pop-off valve opens: during expiration for spontaneous ventilation, and during inspiration for controlled ventilation.[206] Due to the location of the fresh gas inflow near the patient, the gas flow patterns of the other Mapleson systems (Fig. 22.40*B–F*) do not differ as markedly between spontaneous and controlled ventilation as that of the Mapleson A.

Relative Efficiencies. The "T-piece" systems DEF are slightly more efficient than systems BC. To prevent rebreathing CO_2, the DEF systems require a fresh gas inflow rate of approximately 2 to 2.5 times minute ventilation, whereas the fresh gas inflow rates required for BC systems are somewhat higher.[203] The reason for this improved efficiency is the location of the pop-off valve relative to the fresh gas inflow. With the BC systems, significant fresh gas is vented through the pop-off at end-expiration (Fig. 22.40*B* and *C*). With the DEF systems, fresh gas flow drives exhaled alveolar gas away from the patient to minimize rebreathing (Fig. 22.40*E* and *F*).[204,205] The relative efficiency of different Mapleson systems with respect to prevention of rebreathing are: A > DFE > CB during spontaneous ventilation, and DFE > BC > A during controlled ventilation.[200,203]

Advantages and Disadvantages. Mapleson systems have low resistance to gas flow, they are small and contain few parts, and changes in the fresh gas flow composition result in rapid changes in the breathing circuit. In addition, the volatile anesthetic agents within a Mapleson breathing circuit have no chance of degradation because of the absence of a CO_2 absorber. However, given their need for higher gas flows to prevent rebreathing, they are not as economical with regards to carrier gas and volatile anesthetic usage as the circle system. Conservation of heat and humidity is less efficient. Finally, scavenging of waste gas can be challenging, with the exception of the Mapleson D, which has the pressure-limiting valve located away from the patient.[205]

Bain Circuit

The Bain circuit is a coaxial circuit and a modification of the Mapleson D system (Fig. 22.41). Fresh gas flows through a narrow inner tube nested within the outer corrugated hose.[207] The central fresh gas tubing enters the corrugated hose near the reservoir bag, but the fresh gas actually empties into the circuit at the patient's end. Exhaled gases pass down the corrugated hose, around the central tubing, and are vented through the pop-off valve near the reservoir bag.[205] Exhaled gases passing down the outer corrugated hose add warmth to the inspired fresh gases by countercurrent heat exchange.

The main hazards related to use of the Bain circuit are an unrecognized disconnection or kinking of the inner fresh gas hose. These problems can cause hypercapnia as a result of inadequate gas flow or increased respiratory resistance. The outer corrugated tube should be transparent to allow ongoing inspection of the inner tube. The integrity of the inner tube can be assessed by sending high-flow oxygen into the circuit while the patient's end is occluded until the reservoir bag is filled.[208] The patient's end is then opened, while oxygen is flushed into the circuit. If the inner tube is intact, the Venturi effect at the patient's end causes a decrease in

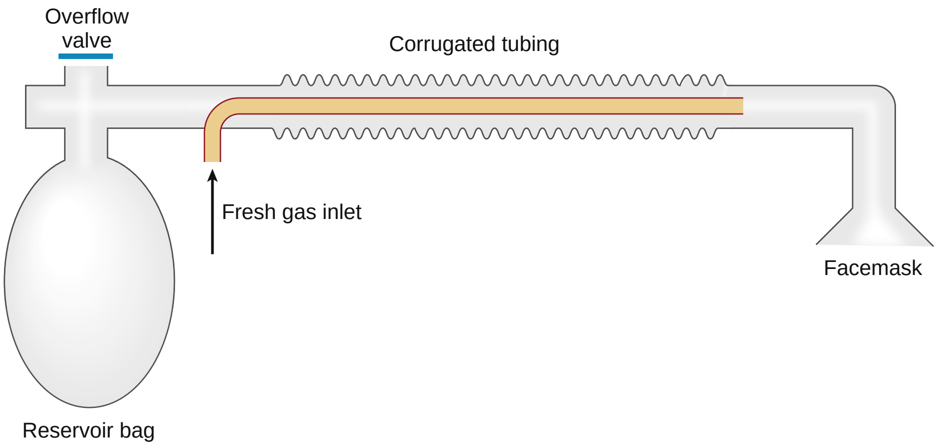

Fig. 22.41 The Bain circuit. (Redrawn from Bain JA, Spoerel WE. A streamlined anaesthetic system. *Can Anaesth Soc J.* 1972;19:426.)

pressure within the circuit, and the reservoir bag deflates. A leak in the inner tube allows fresh gas to escape into the expiratory limb, and the reservoir bag remains inflated. This test is recommended as part of the preanesthesia check if a Bain circuit is used.

Jackson-Rees Circuit. The Mapleson F circuit, also known as the "Jackson-Rees modification of the T-piece," has function similar to the Mapleson D. It incorporates a hole in the end of the reservoir bag distal to the patient for venting of gases (Fig. 22.40*F*). The hole may be occluded by the operator's hand to control bag distension and pressure, or fitted with a pop-off or PEEP valve for more precise control. The Jackson-Rees circuit is convenient for patient transport and preoxygenation during ICU or out-of-the-operating room procedures. The reservoir bag allows for easy tactile and visual monitoring of the patient's respiratory effort. This circuit may be used for spontaneous (with the venting hole open), or assisted/controlled ventilation (with the venting hole partially or totally occluded). The Jackson-Rees is effective when connected to a face mask, endotracheal tube, laryngeal mask airway, or tracheostomy tube.

Like the Bain circuit, the Jackson-Rees has many advantages. It is lightweight, convenient, and potentially reusable (if sterilized). Being a Mapleson system, it has low resistance work of breathing. Fresh gas flows required to prevent rebreathing are approximately 2.5 to 3 times minute volume for spontaneous breathing, and 1.5 to 2 times minute volume for controlled ventilation.[204a] Scavenging of gases from the expiratory valve is possible because the hole or valve is located away from the patient. Caution is advised when using HME filters between these Mapleson circuits and an endotracheal tube. Filters increase resistance and direct fresh gas flow away from the patient. An obstructed antimicrobial filter may produce hypoventilation and hypoxemia and mimic the signs and symptoms of severe bronchospasm.[209]

Self-Inflating Manual Resuscitators

While rarely used for delivery of inhaled anesthetics in modern practice, the manual resuscitation bag (e.g., Ambu bag, Laerdal resuscitator, or simply bag-valve-mask device) is an essential part of every anesthesia workstation. The key feature of this device is a compressible reservoir, typically made of silicone, that automatically expands upon release. Unlike the Mapleson circuits, the self-inflating manual resuscitator may be used for hand ventilation in the absence of an oxygen or air source. These devices are ubiquitous for patient transport, cardiopulmonary resuscitation, and for emergency back-up should the anesthesia machine ventilator or oxygen supply fail (see section on Checking Your Anesthesia Workstation).

In addition to the self-inflating reservoir bag, the manual resuscitator has several key components.[134b] (1) A T-shaped *nonrebreathing valve* is located between the bag and the patient in order to direct gas flow throughout the respiratory cycle. During inspiration, the valve opens to allow flow from the reservoir bag to the patient, and the expiratory port is blocked (see Fig. 22.42). During exhalation, the inspiratory port (to the bag) is blocked, and the expiratory port opens to vent alveolar gas to atmosphere. A variety of valve types exist (e.g., spring-disc, fishmouth). (2) An *inlet valve* permits refilling of the bag with reservoir gas or room air. (3) A *pop-off* valve may be present to limit the PIP, which can easily reach high levels with these devices.[209a] ISO standards require that manual resuscitators designed for infants or children have a valve to limit PIP to 45 cm H_2O.[209b] An override feature must be present should higher pressures be required (in case of poor lung compliance or high endotracheal tube resistance), and use of a manometer is recommended.

While manual resuscitators are extremely useful, portable, and convenient, they do have potential hazards.[134b] Dangerously high inspiratory pressures may be generated if the operator is untrained, uncareful, or if valve failure occurs.[209c] High pressures may lead to barotrauma or gastric insufflation. Similar to Mapleson circuits, significant variation of tidal volume, PIP, and PEEP is likely to occur when manual resuscitators are compared with mechanical ventilators.[209d] Finally, the nonrebreathing valves generate resistance and may significantly increase the work of breathing during spontaneous ventilation.

ANESTHESIA VENTILATORS

Automatic ventilation began to be added to anesthesia machines after the Second World War.[209e] Historical drawover systems relied only on spontaneous breathing by the patient. Later, breathing bags were added to anesthetic delivery devices to allow positive-pressure ventilation. Today's anesthesia workstation ventilators incorporate ICU-like capabilities, including a variety of ventilation modes and the ability to allow for patient triggering. While ICU ventilators are simply open circuit, using entirely fresh gas for each breath, and venting all exhaled gas into the atmosphere, the anesthesia workstation must incorporate a means of collecting and redelivering the patient's exhaled gas in the semi-closed circle system. This requirement presents unique engineering challenges in the design and control of the anesthesia ventilator. Historically the most common solution to this challenge has been the inclusion of a bellow in the anesthesia workstation. Alternative engineering solutions to allow rebreathing include piston-type ventilators, the Maquet volume reflector, or the Draeger Perseus' turbine ventilator. The following discussion focuses on the classification, operating principles, and hazards associated with contemporary anesthesia ventilators.

Classification

Modern anesthesia ventilators can be best classified as either bellows or nonbellows. In bellows ventilators, the bellows serves as a volume reservoir for breathing gas, and the ventilator uses a double-circuit "bag in a bottle" design to deliver breaths. The bellows are typically driven pneumatically. Bellows-type ventilators can be subclassified as ascending or descending. The direction of bellows movement during the *expiratory phase* determines the bellows classification. An ascending (standing) bellows *ascends* during the expiratory phase, whereas a descending (hanging) bellows *descends* during the expiratory phase. Both types of bellows ventilators are illustrated in Fig. 22.43*A* and *B*. In nonbellows machines, the reservoir function may be served by the breathing bag itself (as in Draeger piston

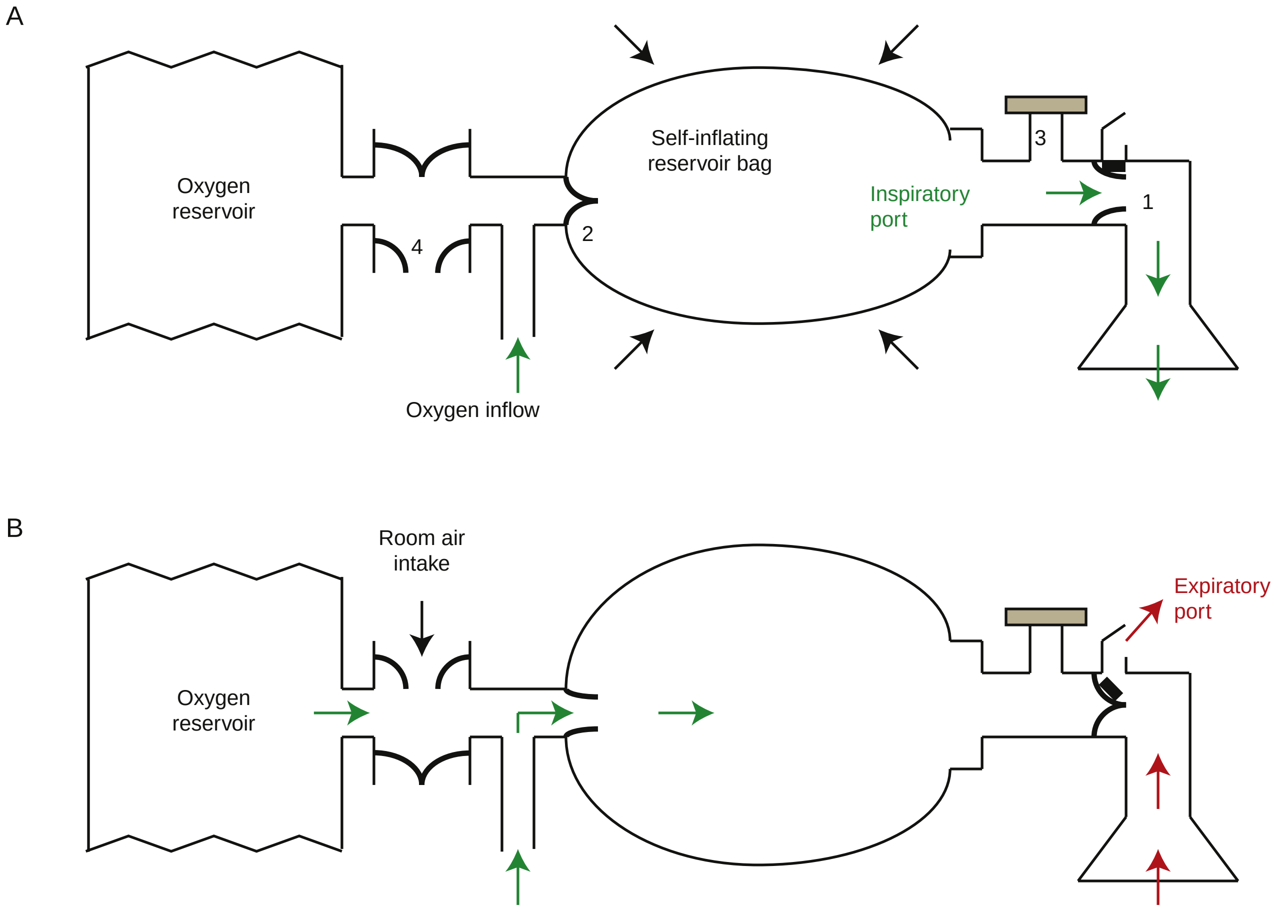

Fig. 22.42 Self-inflating manual resuscitator. (A) Flow of gas during inspiration. (1) Nonrebreathing valve, (2) bag inlet valve, (3) pop-off or pressure limiting valve (standard for pediatric and infant devices), and (4) outflow or excess-oxygen venting valve. (B) Flow of gas during expiration. See text for details. (Redrawn after Dorsch JA, Dorsch SE. The anesthesia machine. In Dorsch JA, Dorsch SE, eds. *Understanding Anesthesia Equipment.* 5th ed. Baltimore: Williams & Wilkins; 2008:83, Chapter 10 Manual Resuscitators; and Lien S, Verreault DJ, Alston TA. [see Fig. 22.43*C*] or turbine ventilators) or by the "volume reflector," in the Maquet Flow-i anesthesia workstation. The drive mechanism of piston and turbine ventilators is mechanical, while the Maquet ventilator is pneumatically driven.

Additional classifications involve the modes of ventilation that are available. Older anesthesia machine ventilators operated only in a time-cycled manner, or as "controller ventilators," without the ability to respond to a patient's spontaneous breathing efforts. Modern machines that offer synchronized intermittent mandatory ventilation (SIMV), assist/control (A/C), and pressure support ventilation (PSV) must offer the ability for the patient to trigger breaths, and are referred to as "controller/noncontroller" ventilators. In contemporary anesthesia workstations, the responsiveness to patient triggering efforts is comparable to ICU ventilators, but the clinician should be on the lookout for evidence of asynchrony in modes that allow triggering.[209f,209g] Contemporary anesthesia ventilators can function in volume-controlled or pressure-controlled modes. Finally, even though some ventilators may be pneumatically driven, all modern ventilators are under electronic control. The design of different anesthesia ventilators, with an emphasis on the integration between the ventilator and the circle breathing system, using specific workstations as examples are discussed below.

Pneumatically Driven Bellows Ventilator

The operating principle of the bellows ventilator is that it functions in a rigid airtight housing and serves as a reservoir for the patient's breathing gas. The driving force used to move gas from the bellows back to the patient is pressurized gas that flows into the bellows' housing under electropneumatic control. The bellows fills with the patient's exhalation and fresh gas flow. Once the bellows is refilled, excess circuit gas is vented to the scavenging system during the expiratory pause. The mechanisms that vent breathing circuit waste gas during mechanical ventilation with bellows ventilators differ among manufacturers and models. The bellows ventilator is traditionally designated as a *double circuit*, meaning that the ventilator drive gas and the breathing gas exist in two separate circuits. The bellows serves as the interface between the breathing gas and the drive gas, much like the reservoir bag serves as the interface between the breathing gas and the anesthesia care provider's hands.[209h] Figs. 22.44 and 22.45 illustrate the inspiratory and expiratory phases of mechanical ventilation with an ascending bellows ventilator on the GE Aisys workstation. Note that the bellows ventilator uses pressurized gas from the intermediate-pressure section of the anesthesia machine to drive the bellows. On older bellows ventilators,

Fig. 22.43 Three types of anesthesia ventilators during exhalation *(left)* and inhalation *(middle)*, with photo *(right)*. To allow rebreathing and conservation of anesthetic gases, the anesthesia workstation ventilator must have a reservoir for the patient's exhaled breathing gas, just as the breathing bag does in manual and spontaneous modes of ventilation. This is a unique requirement of ventilators in anesthesia workstations. Intensive care unit ventilators, conversely, can simply vent exhaled gases into the environment. In the diagrams, breathing gas is green and ventilator drive gas is yellow. (A) Ascending bellows. (B) Descending (hanging) bellows. (C) Piston ventilator. See text for additional details. (Piston ventilator diagram modified from Yoder M. Ventilators. In: *Understanding Modern Anesthesia Systems.* Telford, PA: Dräger Medical; 2009.)

the user selected a tidal volume by setting a physical stop that restricted the bellows' filling (return stroke) to that point, making it a volume control ventilator.[131a] The modern bellows ventilator has primary control over the pressure applied to the bellows, and uses data integrated from the flow sensors to create volume control breaths.

The source of the drive gas for the bellows is either oxygen or air, which is obtained from the gas supply section of the workstation. Some workstations allow for the selection of either oxygen or air as the ventilator drive gas, and some can entrain room air through a Venturi effect into the oxygen drive gas flow, thereby decreasing the oxygen gas requirement. Knowing the type of gas used to drive the bellows ventilator can be important in oxygen failure emergencies. If oxygen is used as the drive gas, then the amount of oxygen consumed by the anesthesia machine will equal the amount of oxygen selected for fresh gas flow *plus* an amount approximately equal to the minute ventilation being delivered by the ventilator. Whereas a full E-cylinder can provide 10 hours of use with oxygen fresh gas flow of 1 L/min and manual ventilation through the circle system, that same E-cylinder will provide less than 2 hours' supply in an adult patient when oxygen is used as the ventilator drive gas.

The ventilator drive gas circuit is located outside the bellows, and the patient's breathing circuit is inside the bellows. During the inspiratory phase the electronically controlled ventilator driving gas enters the bellows chamber and causes the pressure to increase, thereby compressing the bellows, which delivers gas to the patient's lungs. The drive gas also closes the exhalation valve and prevents the breathing gas from escaping into the scavenging system. Compensation for the impact of fresh gas flow on tidal volume accuracy is accomplished by monitoring the inhaled tidal volumes and adjusting ventilator drive gas volumes accordingly. *APL,* Adjustable pressure-limiting; *CO_2,* carbon dioxide. Fig. 22.45 During the early expiratory phase, the patient is able to exhale into the bellows because the ventilator exhalation valve is now open, thus allowing the drive gas in the bellows housing to vent through the scavenger outlet. The pop-off or ventilator relief valve prevents bellows gas from escaping at this point so the bellows can fill. In the late expiratory phase, positive end-expiratory pressure (PEEP) is provided by pressurization of the bellows housing and pressure modulation of the expiratory valve. (Courtesy Dr. Michael A. Olympio; modified with his permission. Adapted with permission from Datex-Ohmeda. *Aisys Anesthesia Machine: Technical Reference.* Madison, WI: Datex-Ohmeda; 2005.)

As described earlier, bellows-type ventilators can be classified according to the direction that they move during patient exhalation. Ascending bellows rise with exhalation, and descending bellows fall with exhalation (see Fig. 22.43). Older pneumatic ventilators and some newer anesthesia workstations use weighted descending bellows, but most contemporary bellows ventilators employ an ascending bellows design. Of the two configurations, the ascending bellows is considered safer. An ascending bellows will not fill if total disconnection occurs, or it may only partially fill if a circuit leak exceeds the fresh gas flow rate, providing an important visual cue for a circuit disconnect or leak. The bellows of a descending bellows ventilator, on the other hand, will continue its regular upward and downward movement despite patient disconnection: the drive gas pushes the bellows upward during the inspiratory phase, and during the expiratory phase the bellows "fills" with entrained room air instead of the patient's exhaled gas, because of the weighted bellows. The pressure monitor and the volume monitor may be fooled even if disconnection is complete.[36] An essential safety feature of any anesthesia workstation that uses a descending bellows is an integrated CO_2 apnea alarm that cannot be disabled while the ventilator is in use.

Problems With Bellows Ventilators. Correct function of the bellows ventilator requires that both the bellows housing and the bellows itself be free of leaks. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas is vented to the atmosphere.[209i] A hole in the bellows can lead to alveolar hyperinflation and possibly barotrauma in some ventilators because high-pressure driving gas can enter the patient's circuit. The oxygen concentration of the patient's gas may increase when the driving gas is 100% oxygen, or it may decrease if the driving gas is composed of air or an air-oxygen mixture.[210]

The ventilator relief valve (sometimes called the "exhalation valve"; see Fig. 22.44) can potentially cause problems. The function of this valve is to open during exhalation once the bellows has refilled, venting excess gas to the scavenger outlet. Hypoventilation can occur if the valve becomes incompetent because anesthetic gas is delivered to the scavenging system instead of to the patient during the inspiratory phase. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or a damaged flapper valve.[211,212] A ventilator relief valve stuck in the closed or partially closed position can cause either barotrauma or undesired PEEP.[213] Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases.[37] In this case, breathing circuit pressure escalates because the excess anesthetic gas cannot be vented. A number of manufacturers' bellows-style anesthesia workstations send the used ventilator drive gas to the anesthesia gas scavenging system during exhalation. Under certain conditions, notably high fresh gas flows combined with high minute ventilation, the scavenging system can be overwhelmed, causing inadvertent high PEEP levels and/or pollution of the operating room with waste anesthetic gases (see section on scavenging systems). Other mechanical problems that can occur include leaks within the system, faulty pressure regulators, and faulty valves.

Mechanically Driven Piston Ventilator

Mechanically driven, electronically controlled piston-type ventilators use a computer-controlled stepper motor instead of compressed drive gas to deliver tidal volume (see Fig. 22.43). These are *single-circuit* ventilators, because there is not a separate ventilator drive gas circuit. The piston operates much like the plunger of a syringe in a cylinder of essentially zero compliance.[131a] The ventilator has primary control over the volume displaced in the circuit and uses the data from pressure sensors to create pressure control breaths. The computerized controls can support a variety of ventilator modes, including pressure or volume limited breaths, in controlled, synchronized, or spontaneous modes.

Because the patient's mechanical breath is delivered without the use of compressed gas to actuate a bellows, these systems consume dramatically less compressed gas during ventilator operation than do traditional pneumatic ventilators. This improvement in efficiency may have clinical significance when the anesthesia workstation is used in a setting where no pipeline gas supply is available (e.g., remote locations or office-based anesthesia practices). Another advantage of the piston ventilator is the potential for very accurate tidal volume delivery, because of the low compliance of the piston chamber. This is in contrast to bellows-type ventilators, in which the drive gas can be subject to varying degrees of compression. With either piston or bellows ventilators, feedback mechanisms that help maintain stable tidal volume delivery include circuit compliance compensation and the use of inspired tidal volume measurement as a feedback signal.

Figs. 22.46 and 22.47 illustrate the inspiratory and expiratory phases of mechanical ventilation with a piston ventilator, the Dräger Fabius workstation. Note the location of the ventilator within the breathing circuit between the fresh gas inflow and the inspiratory valve. The breathing bag participates in the circuit during mechanical ventilation, acting as the reservoir for rebreathing. The circuit employs a *fresh gas decoupling valve* to exclude fresh gas from being added to the tidal volume during inspiration. Therefore during inspiration the fresh gas is added to the breathing bag. During the expiratory phase, the breathing bag initially fills with exhaled gas; then, as the piston returns to its starting position, the fresh gas decoupling valve opens, and fresh gas flow plus gas from the breathing bag refill the piston chamber.

The piston in a piston ventilator tends to be fully or partially concealed from view, unlike the bellows on a bellows ventilator. The piston ventilator therefore does not naturally provide the visual feedback of a circuit disconnect or leak that is provided by the ascending bellows. However, the breathing bag, which serves as the reservoir during mechanical ventilation, moves with patient ventilation and can visually alert the provider to disconnect.

Additional feedback mechanisms have been incorporated on particular machines. For example, the Dräger Fabius Tiro has a transparent piston housing so that the user can visualize the motion of the piston, and the Dräger Apollo can be programmed to emit a breathing sound with the movement of the piston to provide an auditory cue.

A potential hazard associated with piston ventilators is that, like descending bellows ventilators, they will refill

Fig. 22.46 Inspiratory phase of ventilation with a piston ventilator represented by Dräger Fabius anesthesia workstation. During inspiration, the positive end-expiratory pressure *(PEEP)*/maximum pressure *(P_{max})* valve is held closed. The pressure in the breathing circuit that is generated by the ventilator closes the fresh gas decoupling valve. This directs fresh gas flow toward the breathing bag during inspiration so it does not interfere with tidal volume accuracy. Excess fresh gas flows past the open adjustable pressure-limiting *(APL)* bypass valve, through the exhaust check valve, and to the scavenger. Note how the breathing bag is integral to circuit function during mechanical ventilation. In the manual and spontaneous modes of ventilation, the piston ventilator is held in the upward position, and the APL bypass valve closes, thus making the APL valve operable. (Courtesy Dr. Michael A. Olympio; modified with his permission. Adapted from Dräger Medical. *Dräger Technical Service Manual: Fabius GS Anesthesia System.* Telford, PA: Rev: E, Dräger Medical; 2002.)

Fig. 22.47 During the initial phase of exhalation, before the piston begins moving back to starting position and the decoupling valve opens, the patient exhales into the breathing bag, and fresh gas continues to flow retrograde (not pictured). Once the decoupling valve opens, the piston's movement back to its starting position draws in gas stored within the breathing bag and fresh gas from the fresh gas inflow. Positive end-expiratory pressure (PEEP) is maintained by the PEEP/maximum pressure valve, which also prevents the ventilator from pulling in gas from the lungs. Once the piston reaches the bottom of its stroke, fresh gas flow reverses course and flows in retrograde fashion toward the breathing bag and the absorber (as in Fig. 22.46). Excess gas vents through the exhaust valve to the scavenger (Fig. 22.46). *APL,* Adjustable pressure-limiting. (Courtesy Dr. Michael A. Olympio; modified with his permission. even if a circuit disconnection occurs. Similarly, if a circuit leak is present, piston ventilators may entrain room air through the leak, thereby diluting oxygen and anesthetic agent. The associated risks are hypoxemia and awareness. The Dräger Fabius series piston ventilator will entrain room air through an auxiliary air valve, seen in Fig. 22.43, to fill the piston chamber if the fresh gas flow fails or is inadequate (instead of causing negative pressure in the breathing circuit). However, if this occurs, an alarm will alert the operator. A positive-pressure relief valve on the ventilator prevents excessively high breathing circuit pressure (60-80 cm H_2O).[131a]

Maquet FLOW-i Anesthesia System With Volume Reflector

The Maquet FLOW-i anesthesia workstation uses a novel device called the *volume reflector* (Figs. 22.48 and 22.49) to act as the reservoir. The volume reflector is essentially a long plastic tube with a volume of 1.2 L, coiled compactly to fit in the anesthesia workstation. The volume reflector is functional and "in-circuit" during all modes of ventilation. It is interposed between the patient and the reflector gas module during positive-pressure ventilation or between the patient and the breathing bag during spontaneous or assisted ventilation. The volume reflector therefore acts as a volume reservoir while at the same time preventing mixing between the gas at the two ends of the tube.

Mechanical ventilation is powered by the r*eflector gas module*, a solenoid-controlled oxygen flow source, which pushes gas out of the volume reflector through the CO_2 absorber and to the patient during inspiration, much like a piston (see Fig. 22.48). To understand the function of the volume reflector and reflector gas module, it is convenient to start with the expiratory phase (see Fig. 22.49), where exhaled patient gas fills the volume reflector's proximal end (nearest the patient), displacing reflector gas module gas out the PEEP valve and into the scavenging system. At the end of exhalation, the volume reflector is filled at the patient end with exhaled gas and is filled distally with a mixture of exhaled gases and reflector gas. The coiled design of the volume reflector prevents significant mixing between these gases of different compositions. The inspired tidal volume is generated by a combination of gas from the fresh gas modules and the reflector gas module, which work together in a coordinated manner to control gas flow and pressure in the breathing circuit so that operator-determined ventilation parameters are maintained. During mechanical ventilation on the FLOW-i, the fresh gas flow is not constant, but rather occurs primarily during inspiration. The inhaled anesthetic, if chosen, is injected into this flow (see earlier section on **Injection-Type Vaporizers**). All the gas modules use feedback loop–controlled, solenoid-actuated, pneumatic valves similar in function to those found in a servo-controlled ICU ventilator.[214]

When the workstation is in the spontaneous mode of ventilation, the breathing bag is enabled, and the reflector gas module is disabled. The patient breathes in and out of the volume reflector, and circuit pressure is controlled by the operator-adjustable APL valve. Excess gases in controlled and spontaneous modes of ventilation are vented to the scavenger through the dual-function PEEP-APL valve.

The FLOW-i system can compensate for breathing system leaks by increasing reflector gas module flow. The operator is informed if this occurs. Because the reflector gas module provides only 100% oxygen, dilution of anesthetic gas occurs in this circumstance. The machine is nearly entirely electronically interfaced; therefore an emergency manual ventilation backup mode is provided for cases of system failure. This emergency backup mode provides an oxygen flow meter and mechanical APL valve linked to the patient circuit.[214]

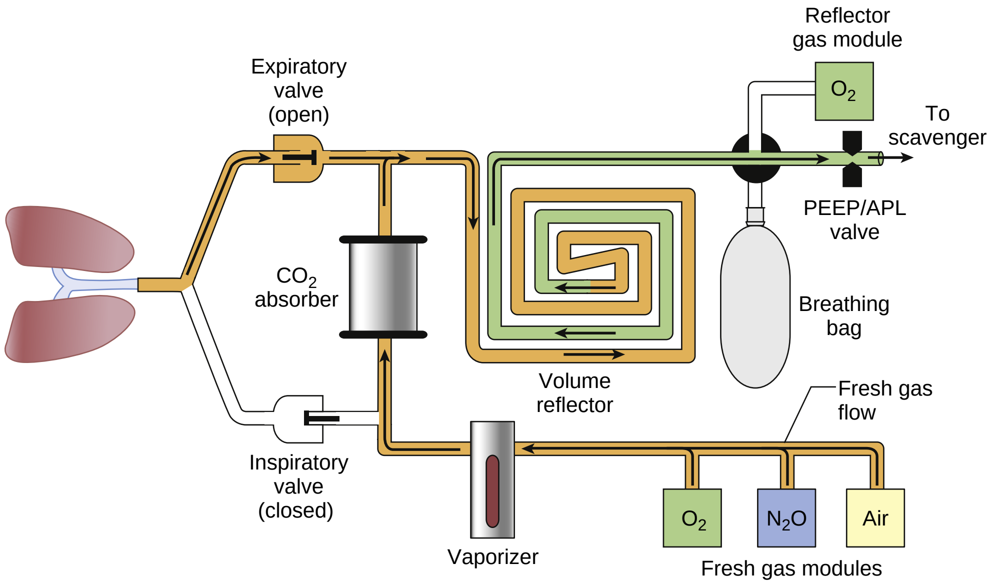

Fig. 22.49 Maquet FLOW-i breathing circuit and gas supply during exhalation in a controlled ventilation mode. The patient exhales into the volume reflector, which serves as an exhalation reservoir. The patient only partially fills the volume reflector. Fresh gas flows in retrograde fashion and combines with the exhaled gas. Excess gas is vented to the scavenger through the positive end-expiratory pressure *(PEEP)*/adjustable pressure-limiting *(APL)* valve, which also controls breathing circuit pressure (PEEP). When the machine is placed in the manual mode of ventilation, the breathing bag is enabled and the reflector gas module is disabled. In the manual mode, the patient breathes in and out of the volume reflector and can be assisted with the breathing bag. The PEEP/APL valve vents excess gas to the scavenger and controls breathing circuit pressure (continuous positive airway pressure). *CO_2,* Carbon dioxide, *N_2O,* nitrous oxide; *O_2,* oxygen. (Adapted from Maquet Critical Care. *User's Manual: FLOW-i 1.2 Anesthesia System.* Solna, Sweden: Rev: 11, Maquet Critical Care; 2011.)

Dräger Anesthesia Systems With Turbine Ventilators

A number of newer ventilators designed for the ICU utilize turbine technology to generate mechanical ventilation. Turbine ventilators use mechanical energy to spin a small turbine (fan) at very high speeds to create pressure and flow. Some possible functional advantages of turbine-based ventilators mentioned in bench testing include better responsiveness to patient triggering, more effective PSV, and, in some cases, more accurate tidal volume delivery under high ventilatory workload.[214a,214b,214c]

The Dräger Zeus and Perseus workstations incorporate turbine-type ventilators (Figs. 22.50 and 22.51). In constructing an anesthesia workstation, the major advantage of the turbine is that it can be placed directly within the circle system. Unlike the bellows or volume reflector, it does not require a separate quantity of gas to move the patient's tidal volume; and unlike a piston, it does not require refilling. During inspiration (see Fig. 22.50), the turbine blower generates flow and pressure directed into the inspiratory limb of the patient circuit, drawing gas from the breathing bag, which serves as a reservoir during mechanical ventilation. The fresh gas flow is incorporated as part of this inspiratory flow. During exhalation (see Fig. 22.51), exhaled gas fills the bag before escaping to the scavenge system, and that portion of the fresh gas flow that occurs during exhalation travels in the reverse direction toward the bag as well. As in the piston ventilators, the breathing bag is an integral part of the circuit during mechanical ventilation, continuing to serve a reservoir function. Unlike the piston ventilators, the turbine ventilator design implies that the breathing bag empties during inspiration and refills during expiration. The bag's motion may serve as a visual indicator of ventilation, and depending on set fresh gas flow, of circuit leak.

Unlike the piston, the turbine is primarily a pressure generator. The ventilator utilizes flow sensors and electronic controls to generate a number of modes of mechanical ventilation, including volume and pressure control, pressure support, and airway pressure release ventilation. In the spontaneous mode of ventilation, the operator may dial in a CPAP level.

Target-Controlled Inhalational Anesthesia

During traditional operation of the anesthetic workstation, the anesthesia provider controls the composition of the fresh gas flow that is added to the circle system every minute. Since this fresh gas mixes with the gases already in the circle breathing system, there may be a significant difference between the composition of the fresh gas flow and the final concentration of the inspired (or expired) gases. As the fresh gas flow is decreased, there may be a greater difference between the fresh gas composition and the actual inspired concentrations. If the oxygen in the fresh gas flow is less than the patient's metabolic oxygen requirement, then the amount of oxygen extracted from the circle breathing circuit every minute is more than the amount added, and the inspired gas will eventually become hypoxic.[214d] Reducing the fresh gas flow reduces the total amount of anesthetic agent used, which reduces cost and the environmental footprint. However, low-flow anesthesia can be challenging in practice, as it is easier to control the patient's actual inspired gas composition when the fresh gas flow is high.

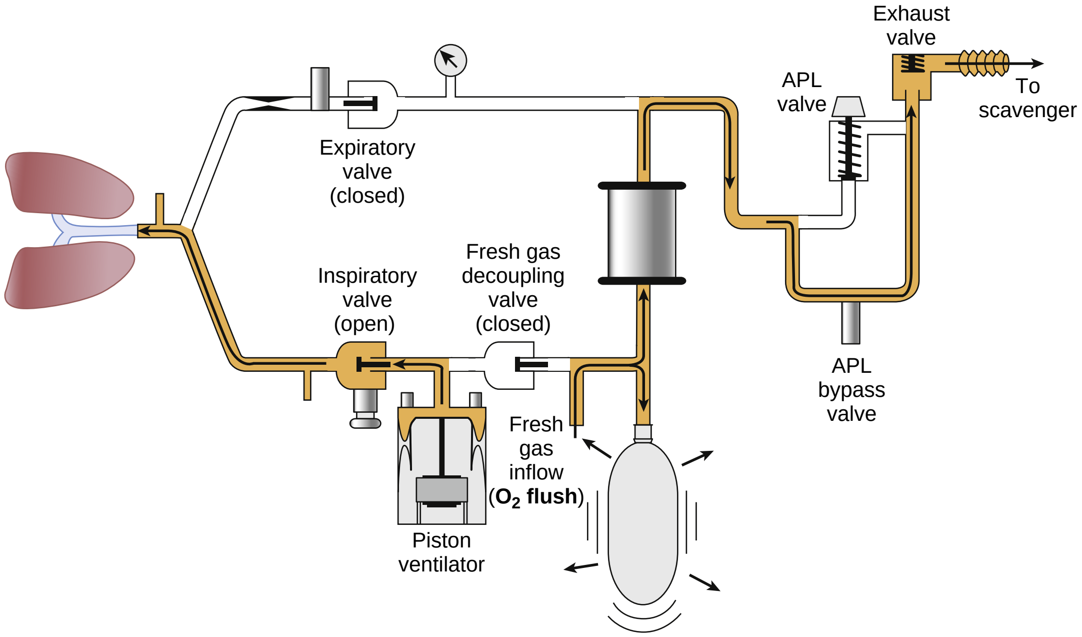

Fig. 22.52 Fresh gas decoupling during an oxygen *(O_2)* flush shown on the Dräger Fabius workstation. During inspiration the positive end-expiratory pressure/maximum pressure valve is held closed. The pressure in the breathing circuit that is generated by the ventilator closes the fresh gas decoupling valve. This directs the high-volume oxygen flush flow toward the breathing bag during inspiration so it does not contribute to inhaled tidal volume and breathing circuit pressure. The O_2 flush gas also flows past the open adjustable pressure-limiting *(APL)* bypass valve, through the exhaust check valve, and to the scavenger. (Modified image courtesy of Dr. Michael A. Olympio. Adapted from Dräger Medical: *Dräger Technical Service Manual: Fabius GS Anesthesia System.* Rev: E. Telford, PA: Dräger Medical; 2002.)

control, it is possible to implement *target-controlled inhalational anesthesia.* The targets subject to control are the end-tidal anesthetic agent and the end-tidal oxygen concentration. Currently, Dräger, GE, and Maquet all have target-controlled systems available. The major advantage of the target control is reduced consumption of anesthetic agent.[214f-214h] These systems rely on proprietary algorithms, and the actual savings may depend on how fast the algorithm tries to achieve the desired anesthetic depth. The target-controlled system might actually prioritize rapid achievement of set anesthetic agent (requiring high initial fresh gas flow) over reducing fresh gas flow and anesthetic agent consumption.[214i] The benefits of low-flow anesthesia could be realized by a vigilant anesthesia provider, but at the expense of significantly more key-strokes per case.[214h] Although the target-controlled modes of inhalational anesthesia seem likely to reduce anesthetic agent use, and to provide an additional layer of patient safety in low-flow anesthesia, none are currently approved by the FDA for use in the United States.

Fresh Gas Flow Compensation and Fresh Gas Decoupling

On older bellows-type anesthesia workstations, the portion of fresh gas flow that occurred during an inspiratory cycle was added to the set tidal volume, leading to variation in tidal volume depending on the set fresh gas flow. During the inspiratory phase of mechanical ventilation, the ventilator relief valve (also known as the ventilator pop-off valve) is typically closed, and the breathing system's APL valve is most commonly out of circuit. Therefore during positive-pressure ventilation, the patient's lungs received the volume from the bellows in addition to that from the flowmeters during the inspiratory phase. The amount of excess volume (and pressure) that the patient received was proportional to the direction and magnitude of the change in the fresh gas flow rate. As the practitioner turned up the fresh gas flow, the tidal volume increased. The opposite would occur if the flow rate were decreased from the baseline. It was therefore common knowledge that the operator needed to adjust the set tidal volume on the ventilator if the total fresh gas flow rate was changed to maintain stable tidal volumes and airway pressure.

Newer workstations have engineering features that provide compensation of fresh gas flow to maintain stable tidal volume delivery. Broadly speaking, the workstation will either exclude the fresh gas from the inspiratory limb of the circuit during inspiration, or it will use electronic controls to compensate for the fresh gas flow's contribution. The precise manner in which this is accomplished accounts for much of the variation in breathing system design. On the Dräger Fabius workstation, a principle called *fresh gas decoupling* is used to prevent changes in the fresh gas flow rate from altering positive-pressure tidal volumes and breathing circuit pressures. During the inspiratory phase of ventilation, a decoupling valve located upstream from the piston ventilator diverts the fresh gas stream toward the breathing bag and scavenge outlet during each positive-pressure breath (Fig. 22.52). The GE Aisys system, on the other hand, uses inspiratory tidal volume measurement as a feedback signal for the automatic adjustment of ventilator drive gas volume to compensate for changes in fresh gas flow and leaks.[214j]

On workstations without a fresh gas decoupling feature, inappropriate activation of the oxygen flush valve during the inspiratory phase of mechanical ventilation can add a substantial amount of volume to the circuit and can result in baro- and/or volutrauma because excess pressure and volume may not be able to be vented from the breathing circuit.[25] Although the circuit high-pressure alarm may provide warning, unless an adjustable inspiratory pressure limiter is set to a relatively low value, high pressures can be realized. On workstations equipped with adjustable inspiratory pressure limiters, maximal inspiratory pressure may be set by the user to a desired peak airway pressure. An adjustable pressure relief valve opens when the predetermined user-selected pressure is reached. This theoretically prevents the generation of excessive airway pressure. However, this feature depends on having preset the appropriate pop-off pressure. If the setting is too low, insufficient pressure for ventilation may be generated and can result in inadequate minute ventilation; if set too high, the excessive airway pressure may still occur and result in patient harm. Some machines may also include a factory-preset inspiratory pressure safety valve that opens at a preset airway pressure, such as 60 to 80 cm H_2O, to minimize the risk of barotrauma. Therefore modern workstations without fresh gas decoupling usually reach a maximum pressure limit and terminate ventilation, release pressure, or sustain at the pressure limit.[215] In machines with a fresh gas decoupling feature, the oxygen flush inflow is diverted away from the patient during positive-pressure ventilation, thereby maintaining stable volumes and pressures.

SCAVENGING SYSTEMS

Scavenging is the collection and subsequent removal of waste anesthetic gases from both the anesthesia machine and the anesthetizing location. Scavenging is required because the fresh gas flow rates used during most anesthetic regimens deliver more anesthetic agent than necessary, as well as more oxygen than is being consumed. Without scavenging, operating room personnel could be exposed to anesthetic gases, and there could be an increased risk of an oxygen-rich environment supporting combustion.

In 1977, the National Institute for Occupational Safety and Health (NIOSH) prepared a document entitled *Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors.*[216] Although it was maintained that a minimal safe level of exposure could not be defined, the NIOSH proceeded to issue the recommendations shown in Table 22.9. These same criteria remain in place today. Contemporary scavenging systems are governed by standards set forth by the ISO.[11,216a] In 1999, the ASA Task Force on Trace Anesthetic Gases developed a booklet entitled *Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit.* This publication describes the role of regulatory agencies, reviews scavenging and monitoring equipment, and provides recommendations.[217] Finally, the Occupational Safety and Health Administration (OSHA) publishes *Anesthetic Gases: Guidelines for Workplace Exposures* on its website; this document does not establish legal standards, but is a repository of information, guidelines, and references.[217a]

The two major causes of waste gas contamination in the operating room are the anesthetic technique used and equipment issues.[217,218] Regarding the anesthetic technique, causes of operating room contamination include: (1) failure to turn off the gas flow control valves or the vaporizer when the circuit is disconnected from the patient; (2) use of poorly fitting masks; (3) flushing of the circuit into the room; (4) filling of anesthetic vaporizers, particularly if spillage occurs; (5) use of uncuffed endotracheal tubes; and (6) use of breathing circuits other than the circle system. Equipment failure or lack of understanding of proper equipment use can also contribute to operating room contamination. Leaks can occur in the high-pressure hoses, the nitrous oxide tank mounting, the high- or low-pressure circuits of the anesthesia machine, or the circle system, particularly at the CO_2 absorber assembly. The anesthesia care provider must be certain that the room suction and scavenging system is operational and adjusted properly to ensure adequate scavenging. Waste flow from a side-stream gas analyzer (50-250 mL/min) must also be directed to the scavenging system or returned to the breathing system to prevent pollution of the operating room.[217,218]

TABLE 22.9 National Institute for Occupational Safety and Health Recommendations for Trace Anesthetic Gas Levels

Anesthetic Gas	Maximum TWA Concentration (ppm)*
Halogenated agent alone	2
Nitrous oxide	25
Combination of halogenated agent plus nitrous oxide	
Halogenated agent	0.5
Nitrous oxide	25
Dental facilities (nitrous oxide alone)	50

*Time-weighted average sampling, also known as time-integrated sampling, is a sampling method that evaluates the average concentration of anesthetic gas over a prolonged period, such as 1 to 8 hours.

TWA, Time-weighted average.

Classifications and Components

Waste anesthesia gas scavenging systems can be classified as: *active* or *passive*. In active systems, the scavenging system is connected to a vacuum source, such as the hospital's suction system. Passive systems simply vent the waste gas into a heating, ventilation, and air conditioning (HVAC) system or through a hose to the building's exterior through a wall, ceiling, or floor. Passive systems rely only on the slight positive pressure of the gases leaving the gas-collecting assembly to provide the flow. If the passive system vents to an HVAC system, it is mandatory that it be a *nonrecirculating* system. Passive systems are less common in contemporary operating rooms.

Scavenging systems may also be *open* or *closed*. An open scavenging system allows for room air to be entrained into the flow of waste gas, whereas a closed system does not.[219] This distinction is discussed more thoroughly below.

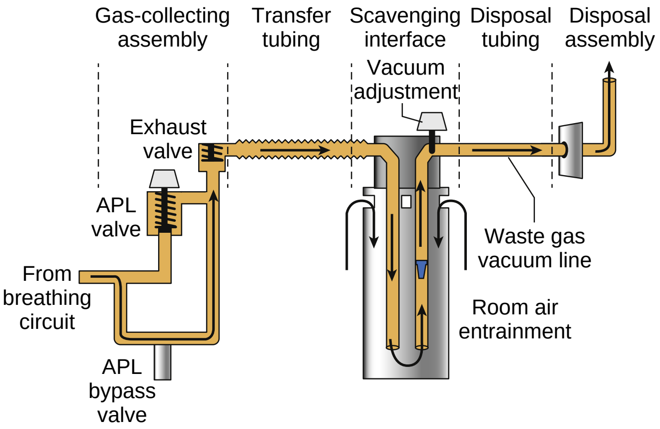

Fig. 22.53 Components of a scavenging system using the example of a Dräger Fabius system (Dräger Medical, Telford, PA) connected to an open, active scavenging system. The transfer tubing has a connector size distinct from the breathing circuit to prevent misconnections. Obstructions in the gas-collecting assembly or transfer tubing can cause high pressure in the breathing circuit. Leaks, inadequate suction, or failure of the scavenging interface can cause environmental contamination. *APL,* Adjustable pressure-limiting. See text for details. (From Brockwell RC. Delivery systems for inhaled anesthesia. In: Barash PG, ed. *Clinical Anesthesia.* 5th ed. Philadelphia: Lippincott Williams & Wilkins; 2006:589.)

Scavenging systems classically have five components (Fig. 22.53): (1) the gas-collecting assembly, (2) the transfer tubing, (3) the scavenging interface, (4) the gas disposal assembly tubing, and (5) an active or passive gas disposal assembly.[220]

Gas-Collecting Assembly. The gas-collecting assemblies are where waste gas exit from the breathing circuit and connect to the transfer tubing. Waste anesthetic gases are vented from the anesthesia system either through the APL valve or through some sort of ventilator relief valve. Excess patient exhaled gas must exit the breathing system through one of these valves or be shed into the room (e.g., poor face-mask fit, endotracheal tube leak, machine leak). Ventilator drive gas on contemporary bellows-type ventilators, as well as the flow from the reflector gas module on the Maquet FLOW-i, are vented via the scavenging system as well. This is significant because under conditions of high fresh gas flow and high minute ventilation, the gases flowing into the scavenging interface may overwhelm the evacuation system. If this occurs, waste anesthetic gases may overflow the system through the positive-pressure relief valve (closed systems) or through the atmospheric vents (open systems) and pollute the operating room. This scenario is less likely with pneumatically driven ventilators that exhaust their drive gas (100% oxygen or oxygen/air mixture) into the operating room through a small vent on the back of the ventilator control housing.

Transfer Tubing. The transfer tubing carries excess gas from the gas-collecting assembly to the scavenging interface. As specified by ISO standard 80601-2-13, the scavenging system must have 30-mm connectors, or some other proprietary connector that will prevent the scavenging system from connecting to other elements on the workstation.[11] Some manufacturers color-code the transfer tubing with yellow bands to distinguish it from 22-mm breathing system tubing. The tubing must be sufficiently rigid to prevent kinking to minimize the chance of occlusion, or it must contain some means of pressure relief in case of occlusion. Occlusion of the transfer tubing can be very problematic because it is upstream from the pressure-limiting features of the scavenging interface. If the transfer tubing is occluded by kinking or misconnection, breathing circuit pressure will increase and barotrauma can occur.[144,221-223] On machines that have separate transfer tubes for the APL valve and for the ventilator relief valve, the two tubes merge before or at the scavenging interface.

Scavenging Interface. The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressure.[220] The interface should limit the pressure immediately downstream from the gas-collecting assembly to between −0.5 and +3.5 cm H_2O under normal working conditions.[11] Positive-pressure relief is mandatory irrespective of the type of disposal system used, so the system can vent excess gas in case of occlusion (or inadequate suction with active systems) downstream from the interface. If the disposal system is an active system, negative-pressure relief will also be necessary to protect the breathing circuit or ventilator from excessive subatmospheric pressure. Subatmospheric pressure in the scavenging system could induce gas flow from the patient's breathing system. A reservoir is highly desirable with active systems because it stores waste gases until the evacuation system can remove them.

OPEN INTERFACES. The open scavenge interface sets up a continual flow into the disposal tubing using an active interface. If the amount of waste gas being discharged from the anesthesia workstation is less than the continual flow in the scavenging system, then the balance of that flow is obtained from entrained room air. Because the anesthesia machine discharges waste gas intermittently in surges, peak flow may overwhelm the flow of the scavenging system, so open systems also require a reservoir canister (Fig. 22.54).[219] Waste gas enters the system at the top of the canister and travels to the bottom through an inner tube, where a vacuum line removes waste gases. When adjusted properly, the vacuum rate should exceed the rate of waste gas flow into the chamber, and some room air should also be drawn into the canister through the relief port. The vacuum flow rate is usually adjusted on the scavenging interface using a flow control valve and flowmeter. Adjusting the scavenger vacuum flow rate is an important part of the workstation daily pre-use checkout procedure. If vacuum flow is inadequate, waste gas can spill out into the room through the relief ports. The open system does not require positive- or negative-pressure relief valves because the canister is open to the atmosphere. Relief ports on the top of the canister provide positive- and negative-pressure relief. Some open scavenging systems can incorporate a reservoir bag instead of a canister.

CLOSED INTERFACES. Closed scavenging interfaces are isolated from the environment by pressure relief valves, so the relationship of waste gas flow, vacuum flow, and the size of the system's reservoir bag determines the effectiveness of the gas elimination. All closed interfaces must have a positive-pressure relief valve to vent excess system pressure in

case of obstruction and a negative-pressure relief valve to protect the breathing system from subatmospheric pressure if an active disposal system is used.[220]

Two types of closed interfaces are used in clinical practice. One is used with passive scavenging systems and has positive-pressure relief only; the other is used with active scavenging systems and has both positive- and negative-pressure relief.

POSITIVE-PRESSURE RELIEF ONLY. A *closed, passive* scavenging system requires only a single positive-pressure relief valve (Fig. 22.55*A*). Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the slight positive pressure of the gases leaving the patient's breathing system because a negative-pressure evacuation system is not used. Waste gases are then passively vented to a nonrecirculating HVAC system or to the outdoors. The positive-pressure relief valve opens at a preset value (such as 5 cm H_2O) if an obstruction between the interface and the disposal system occurs.[224] With this type of system, a reservoir bag is not required.

POSITIVE- AND NEGATIVE-PRESSURE RELIEF. A *closed, active* scavenging system requires a positive-pressure relief valve and at least one negative-pressure relief valve, in addition to a reservoir bag. Fig. 22.55*B*, is a schematic of Dräger Medical's closed scavenge interface for active suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir bag intermittently accumulates excess gas until the evacuation system eliminates it. The operator must adjust the vacuum control valve so that the reservoir bag remains properly inflated (see Fig. 22.55*B*, label *A*), and neither overdistended (label *B*) nor completely deflated (label *C*). Gas is vented to the operating room atmosphere through the positive-pressure relief valve if the system pressure exceeds a preset pressure (varies depending on manufacturer). Room air is entrained through the negative-pressure relief valve if the system pressure is more negative than that valve's opening pressure, approximately −0.5 cm H_2O. Some systems have a backup negative-pressure relief valve that opens at −1.8 cm H_2O if the primary negative-pressure relief valve becomes occluded by dust or other causes. The effectiveness of a closed system in preventing spillage depends on the rate of waste gas inflow, the evacuation flow rate, and the size of the reservoir. Leakage of waste gases into the atmosphere occurs only when the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive-pressure relief valve. A "high PEEP" or sustained airway pressure alarm is often encountered in this circumstance.

Gas Disposal Assembly Conduit or Extract Flow. The gas disposal assembly conduit conducts waste gas from the scavenging interface to the receiving end of the gas disposal system (see Fig. 22.53). It should be collapse-proof and should run overhead, if possible, to minimize the chance of accidental occlusion. The connection to the scavenging interface can be a permanent or proprietary connector, but the connection to an active gas disposal system should be a DISS-type connector.[225]

Gas Disposal System. The gas disposal assembly ultimately eliminates excess waste gas (see Fig. 22.53). The two types of environmental disposal mechanisms, active and passive, have been described.

Hazards

Scavenging systems minimize operating room pollution, yet they add complexity to the anesthesia system. A scavenging system functionally extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Excessive vacuum applied to a scavenging system can cause undesirable negative pressures within the breathing system. Obstruction of scavenging pathways can cause excessive positive pressure in the breathing circuit. Even when the patient is protected from barotrauma by positive-pressure relief valves, alarm conditions can contribute to potentially unsafe conditions.[226] Inadequate vacuum to the interface can cause venting of waste gas into the operating room. An unusual report linked fires in engineering equipment rooms to design of some waste gas scavenging systems in which the waste gases were vented into machine rooms that have vents opening to the outside as opposed to directly outside.[21,230]

BOX 22.3 **Requirements for Safe Delivery of Anesthesia Care**

- Reliable delivery of oxygen at any appropriate concentration up to 100%.
- Reliable means of positive-pressure ventilation.
- Backup ventilation equipment available and functioning.
- Controlled release of positive pressure from the breathing circuit.
- Anesthesia vapor delivery (if intended as part of the anesthetic plan).
- Adequate suction.
- Means to conform to standards for patient monitoring.

From Sub-Committee of American Society of Anesthesiologists Committee on Equipment and Facilities: *Recommendations for Pre-Anesthesia Checkout Procedures* (2008).

Checking Your Anesthesia Workstation

A complete preanesthesia checkout procedure (PAC) must be performed each day before the anesthesia workstation is first used, and an abbreviated version should be performed before each subsequent case. Box 22.3 lists seven basic requirements for safe delivery of anesthesia care drawn from the ASA's *Recommendations for Pre-Anesthesia Checkout Procedures.*[11b] The anesthesia provider must have assurance prior to commencing any anesthetic that these requirements have been met. Institutions should develop and detail local procedures for meeting these basic safety requirements. These local procedures have taken on increased importance as increasing machine diversity make the applicability of a single, generic PAC remote.

Despite the fact that a PAC has been a mandatory part of anesthesia practice for over 30 years,[228] evidence suggests that anesthesia providers frequently do not perform a complete PAC,[6,229] and may miss faults even when explicitly looking for them on a sabotaged machine.[3] Furthermore, all contemporary anesthesia workstations have automated checkout procedures, none of which can assure that all the basic safety requirements for delivery of anesthetic care have been met.[8,231] In their 2008 *Recommendations*, the ASA suggests that many anesthesia providers are not fully aware of what elements are checked by the automated procedures.[11b] Even review of user's manuals does not always make it obvious.

The ASA's *Recommendations for Pre-Anesthesia Checkout Procedures*, summarized in Box 22.4, focus on ensuring the *availability* of key equipment, and assessing the *function* of that equipment. The *Recommendations* also give guidance as to which items may be carried out by a technician (such as an anesthesia technician or biomedical technician). When the party responsible is listed as "provider and technician," then the provider must perform that task; the task may *also* be assigned to the technician as an added layer of safety. Each institution should develop their own procedures in which the specific duties are delineated.

BOX 22.4 Summary Recommendations of the 2008 Preanesthesia Checkout Procedures

Items to Be Completed *Daily*

Item #	Task	Responsible Parties?
1	Verify that auxiliary oxygen cylinder and self-inflating manual ventilation device are available and functioning	Provider *and* technician
2	Verify that patient suction is adequate to clear the airway	Provider *and* technician
3	Turn on the anesthesia delivery system and confirm that AC power is available	Provider *or* technician
4	Verify the availability of required monitors, including alarms	Provider *or* technician
5	Verify that pressure is adequate on the spare oxygen cylinder mounted on the anesthesia machine	Provider *and* technician
6	Verify that the piped gas pressures are ≥50 psig	Provider *and* technician
7	Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed	Provider *only*
8	Verify that the gas supply lines have no leaks between the flowmeters and the common gas outlet	Provider *or* technician
9	Test the scavenging system function	Provider *or* technician
10	Calibrate, or verify the calibration of, the oxygen monitor, and check the low-oxygen alarm	Provider *or* technician
11	Verify that carbon dioxide absorbent is not exhausted	Provider *or* technician
12	Perform breathing system pressure and leak testing	Provider *and* technician
13	Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider *and* technician
14	Document the completion of checkout procedures	Provider *and* technician
15	Confirm the ventilator settings, and evaluate readiness to deliver anesthesia care (Anesthesia Time Out)	Provider *only*

Items to Be Completed Before Each Procedure

Item #	Task	Responsible Parties?
1	Verify that patient suction is adequate to clear the airway	Provider *and* technician
2	Verify the availability of required monitors, including alarms	Provider *or* technician
3	Verify that vaporizers are adequately filled and, if applicable, that the filler ports are tightly closed	Provider only
4	Verify that carbon dioxide absorbent is not exhausted	Provider *or* technician
5	Perform breathing system pressure and leak testing	Provider *and* technician
6	Verify that gas flows properly through the breathing circuit during both inspiration and exhalation	Provider *and* technician
7	Document the completion of checkout procedures	Provider *and* technician
8	Confirm the ventilator settings, and evaluate readiness to deliver anesthesia care (Anesthesia Time Out)	Provider only

Modified from Sub-Committee of American Society of Anesthesiologists Committee on Equipment and Facilities: *Recommendations for Pre-Anesthesia Checkout Procedures* (2008).

2008 RECOMMENDATIONS FOR PRE-ANESTHESIA CHECKOUT PROCEDURES

The items in Box 22.4 are reviewed here. Fifteen items are required before commencing the day's anesthesia procedures. Eight items (see Box 22.4, items 2, 4, 7, 11-15) are required before each case.

Item 1: Verify Auxiliary Oxygen Cylinder and Self-Inflating Manual Ventilation Device Are Available and Functioning

Frequency: Daily
Responsible parties: Provider and technician

The anesthesia provider must always be prepared to keep the patient alive without the assistance of the anesthesia machine. The most important safety check in any anesthesia location prior to commencing the day's procedures is the presence of a self-inflating manual ventilation device and a source of oxygen that is separate from the anesthesia workstation and hospital pipeline oxygen supply. These items must be present at every anesthetizing location. The *Recommendations* advise checking the function of the self-inflating ventilation device; this can typically be done without opening the packaging. Note that the presence of a non–self-inflating Mapleson-type breathing circuit is *not* adequate to meet this item.

The auxiliary oxygen tank, typically an E-cylinder, should be checked to make sure it is full, and also for the presence of an attached flowmeter and a means to open the cylinder valve. After check, the valve should be closed to prevent inadvertent loss of the contents. Ensuring the presence of properly filled portable cylinders with attached flowmeters and cylinder wrenches benefits from the logistical support of support staff, but must ultimately be verified by the anesthesia provider.

Item 2: Verify Patient Suction Is Adequate to Clear the Airway

Frequency: Before each use
Responsible parties: Provider and technician

"Safe anesthetic care requires the immediate availability of suction to clear the airway if needed."[11b] Adequate suction with tubing of appropriate length and an oral suctioning tool (e.g., Yankauer suction tip) are necessary before the start of any case. Since these are normally changed with every case, this item is often shared between provider and technician. The provider must verify this item prior to commencing the anesthetic.

Item 3: Turn on Anesthesia Delivery System and Confirm That AC Power Is Available

Frequency: Daily
Responsible party: Provider or technician

Contemporary anesthesia workstations have backup battery power if wall power should fail. If a case is inadvertently started on battery backup power, the first obvious sign of power failure can be catastrophic system shutdown when the backup batteries are exhausted. Prior to commencing the day's anesthetic procedures, functioning AC power should be verified. The ASA also recommends verifying power supply to component subsystems such as desflurane vaporizers. This item may be completed by technician or provider.

Item 4: Verify Availability of Required Monitors and Check Alarms

Frequency: Before each use
Responsible party: Provider or technician

The ASA *Recommendations* include in this item both the presence of monitoring supplies (blood pressure cuffs of appropriate sizes, pulse oximetry probes, etc.), functional tests of critical monitoring equipment (pulse oximeter and capnography), and functional tests of alarm conditions. The importance of an audible alarm is emphasized.

Some elements of this item are straightforward, such as verifying the availability of the monitoring equipment and making sure that monitors are on and cables are properly plugged in. However, the process of checking alarm thresholds, and possibly resetting them, can be tedious. Monitor alarm settings may possibly vary within individual facilities as a result of provider manipulation of alarms for case requirements, a lack of standard default settings, and failure to reset alarm limits routinely. Departmental alarm default settings can be established and programmed into anesthesia workstation monitors. Alarm limit settings also include anesthesia machine alarms such as volume, pressure, and inspired oxygen concentration limits. The practitioner should ensure that critical alarm limits are set to values that permit these alarms to do what they were intended to do. Here, anesthesia technicians can improve the quality of the pre-use checkout by checking the function of standard monitors and confirming that critical alarm thresholds are set to established default values.

Item 5: Verify That Pressure Is Adequate on the Spare Oxygen Cylinder Mounted on the Anesthesia Machine

Frequency: Daily
Responsible parties: Provider and technician

In addition to verifying the presence of a separate source of cylinder oxygen (Item 1), the anesthesia provider should verify the presence of an adequately filled oxygen cylinder mounted on the anesthesia workstation. Verification of oxygen cylinder pressure is accomplished by opening the oxygen cylinder or cylinders on the back of the machine and evaluating the tank gauge pressure. The current recommendations do not provide a specific value that would prompt replacing the tank, but some manufacturer's manuals suggest changing the oxygen cylinder when the pressure is below 1000 psi.[31a]

The *Recommendations* affirm that other gas supply cylinders such as air, nitrous oxide, etc., need to be checked only if that gas is required for the anesthetic.

Item 6: Verify That Piped Gas Pressures Are 50 psig or Higher

Frequency: Daily
Responsible parties: Provider and technician

A daily check of adequate pipeline pressures is specified in the *Recommendations for Pre-Anesthesia Checkout Procedures*; this item should be performed by the provider even if it is part of the technician's workflow.

A more detailed daily pre-use check of the pipeline system may be part of institutional protocols. For example, a quick daily inspection of connections, supply hoses, gas pressures, and the presence of more than 90% oxygen in the inspiratory limb greatly minimizes risk. An important safety item on all machines is an audible and visual alarm that warns the operator of diminishing oxygen supply pressure. The only way to evaluate this safety device is to disconnect the wall oxygen supply and shut off the oxygen supply tank or tanks, in order to generate the alarm condition. The 2008 *Recommendations* do not mandate this maneuver.

Item 7: Verify That Vaporizers Are Adequately Filled and, If Applicable, That the Filler Ports Are Tightly Closed

Responsible parties: Provider (and technician if redundancy desired)

The anesthesia provider should verify that there is an adequate supply of anesthetic agent in the vaporizer if an inhaled anesthetic is planned. Because not every anesthetic utilizes an inhaled agent, alarm defaults may not include a low agent alarm. The risk of light anesthesia and recall can be mitigated by checking agent levels prior to proceeding.

Loose caps on vaporizer filler ports may be a source of leaks when the vaporizer is on. Because the breathing system pressure and leak test (see Item 12 below) is carried out with the vaporizer off, this source of leak may go otherwise undetected. Some vaporizers are designed to automatically close when the filling adapter is removed. Although not part of the 2008 PAC guidelines, some manufacturers recommend a check of their machine's vaporizer interlock system, which, if present, prevents more than one vaporizer from being activated simultaneously.

Item 8: Verify That No Leaks Are Present in the Gas Supply Lines Between the Flowmeters and the Common Gas Outlet

Frequency: Daily and whenever a vaporizer is changed
Responsible party: Provider or technician

As discussed above, the low-pressure section of the anesthesia workstation, from the flow control valves, through the vaporizers, and to the common gas outlet, is the most vulnerable to leaks. Leaks in this section of the machine can be associated with hypoxemia or patient awareness under anesthesia.[22,24]

Two areas of the low-pressure leak test deserve emphasis. First, some anesthesia workstations include an outlet check valve (see Fig. 22.1). The implication of this check valve is that positive pressure in the breathing circuit *cannot* be

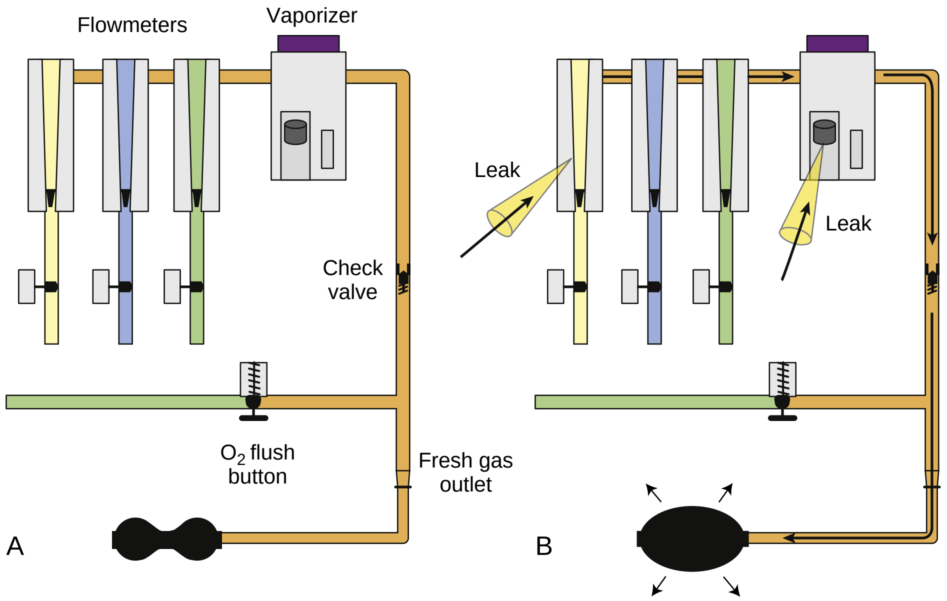

Fig. 22.56 The negative-pressure "universal" low-pressure system leak test. (A) A specially configured suction bulb is connected to the common (fresh) gas outlet and collapsed. Subatmospheric pressure is created in the low pressure circuit, thus opening the outlet check valve (if present) and exposing the vaporizers, tubing, and associated piping and connections to the vacuum. In a system without a leak, the bulb stays deflated. (B) Leaks in the system draw in ambient air and cause the suction bulb to inflate. *O$_2$,* Oxygen.

used to check for leaks upstream in the low-pressure system, because the pressure will not be transmitted past the check valve. On these machines, a negative pressure test must be performed. Second, most vaporizer leaks are not detected unless the vaporizer is on. Therefore a thorough low-pressure leak test can require testing multiple vaporizers, depending on machine configuration. Some workstations (Maquet anesthesia machines and GE Healthcare workstations) do perform automated vaporizer leak testing on their unique vaporizers (ADU vaporizer).

In machines with an outlet check valve, a negative-pressure test must be performed. The negative-pressure leak test is simple to perform and is highly sensitive, detecting leaks as small as 30 mL/min. This simple test requires that the flow control valves be fully closed to prevent any flow of gas into the low-pressure circuit. A specially configured suction bulb, which can either be constructed or obtained from the manufacturer, is then attached to the common gas outlet (Fig. 22.56). The bulb is then squeezed repeatedly until it is fully collapsed. If the bulb does not stay collapsed for a specified period of time, then air is being sucked by the bulb into the machine through a leak that will allow gas to escape when the machine is pressurized. The same maneuver is carried out with each vaporizer opened in turn to check for associated leaks.

The negative-pressure test *can* be performed on machines without a check valve. For this reason, the negative-pressure test is sometimes referred to as the "universal leak test." Several mishaps have resulted from application of the wrong leak test to the wrong machine.[231-234] When in doubt, the negative-pressure test is therefore preferred. However, many of the newer-generation anesthesia machines do not have an accessible common gas outlet; therefore negative-pressure low-pressure system testing cannot be performed. On these machines, either manual positive-pressure testing of the low-pressure system (and vaporizers) is performed during the pre-use checkout, or low-pressure testing is accomplished as part of an automated checkout feature. Note that the automated low-pressure test on some machines needs to be specifically selected.[214j]

Item 9: Test Scavenging System Function

Frequency: Daily
Responsible party: Provider or technician

Evaluation of the scavenging system is a manual maneuver. No automated checks are conducted. A test of the scavenging system begins by checking the proper assembly and integrity of each component and connection within the system including the gas transfer tubes leading from the APL valve and the ventilator relief valve to the scavenging interface. In the case of many modern machines, a single transfer tube may lead from a compact breathing system to the scavenge interface. The integrity of the vacuum tubing leading from the wall outlet to the scavenging interface should also be checked.

To test a closed, passive scavenger system (as seen in Fig. 22.55*A*), one creates high flow within the breathing system by occluding the patient "Y-piece" (or short-circuiting the inspiratory and expiratory limbs of the breathing circuit with breathing hose), occluding the exhaust hose outlet on the scavenging interface, and ensuring that the flow of gas exits the system through the positive-pressure safety relief valve so excess pressure does not build up in the breathing circuit (e.g., <10 cm H_2O). To test a closed, active scavenger system (as seen in Fig. 22.55*B*), two steps are required. A check of positive-pressure relief is conducted as just described for the passive, closed scavenger. Some manufacturers recommend that the suction needle valve be turned off for this step. A check of negative-pressure relief is conducted by setting scavenge interface suction to a routine setting, turning off all flow control valves on the anesthesia machine, and occluding inflow into the patient's breathing circuit at the patient's Y-piece (or short circuiting the inspiratory and expiratory limbs of the breathing circuit with breathing hose) and at the breathing bag mount. At this point, the breathing pressure gauge should indicate a negligible negative pressure (e.g., no lower than −1.0 cm H_2O). Generally speaking, the scavenging suction on active systems should be adjusted so the reservoir bag is never overinflated or underinflated, but it should remain slightly inflated during routine use. Because the volume of gas being passed into the scavenging system varies, it may be necessary to adjust the needle valve. Given the diversity of breathing systems, this check serves as another instance in which users must consider manufacturer-specified protocols when developing a local PAC.

Checking the function of an open, active system as seen in Fig. 22.54 is relatively simple compared with checking a closed, active system. After ensuring that all gas transfer tubes and the suction lines are properly connected, the scavenger suction needle valve is adjusted to place the flowmeter bobbin between the indicator lines. A positive-pressure test and a negative-pressure test are then conducted as described earlier.

Item 10: Calibrate, or Verify Calibration of, the Oxygen Monitor and Check the Low Oxygen Alarm

Frequency: Daily
Responsible party: Provider or technician

The oxygen concentration analyzer is one of the most important monitors on the anesthesia workstation. Older anesthesia workstations used a galvanic cell oxygen sensor located near the patient's breathing circuit inspiratory valve. These devices have a finite life span, which is inversely proportional to the amount of oxygen exposure.[234a] They are also vulnerable to drift. Therefore daily verification of calibration (and recalibration, if necessary) is recommended. Newer anesthesia workstations rely on side-stream multi-gas analyzers to measure the inspired oxygen concentration. The multi-gas analyzer is an irremovable and permanent component of the workstation. Thus it fulfills the requirement imposed on the manufacturer to provide inspired oxygen concentration monitoring. These monitors do not require daily calibration. Nevertheless, the function of the sensor should be checked in room air, to verify that the it reads 21%.

The function of the low-oxygen concentration alarm should be tested daily. This may be done by manually setting the low oxygen concentration alarm limit to more than 21% while exposing the analyzer to room air, generating the alarm condition. A prudent default setting would be somewhere between 25% and 30%, unless oxygen concentrations lower than this value are used routinely. In any case, it is wise to keep it set to at least 21%. These steps may be carried out by a technician, according to local protocols.

Item 11: Verify Carbon Dioxide Absorbent Is Not Exhausted

Frequency: Before each use
Responsible party: Provider or technician

In order to utilize rebreathed gas, the anesthesia circle system requires a CO_2 absorber. Prior to each anesthetic, the absorbent should be assessed for exhaustion. It is important for providers to know that absorbent color change is not as reliable as is the presence of *inspired* CO_2 on capnography in identifying exhausted absorbent. Capnometry should be used with every anesthetic that uses the circle system, and the provider should be vigilant for inspired CO_2 concentration greater than 0. A normal-appearing but nonfunctional absorbent is difficult to detect during the pre-use checkout procedure. It is no longer advised for providers to breathe in and breathe out of the breathing circuit manually to assess the functionality of the absorbent before a case.

Item 12: Breathing System Pressure and Leak Testing

Frequency: Before each use
Responsible parties: Provider and technician

This PAC item verifies that positive pressure can be developed and sustained in the breathing circuit, and that the APL ("pop-off") valve properly relieves pressure in the circuit. It is not rare for either the disposable breathing circuit components or the fixed anesthesia machine components to leak. Therefore a leak check of the breathing system is of paramount importance. Traditionally, this test has been performed manually after an inspection of the breathing circuit, removal of the gas sampling line, and capping of the gas sampling line port. With the machine set in the "bag" or the manual mode of ventilation, the gas flows are set to zero, the APL valve is closed, the patient's Y-piece is occluded, and breathing system is pressurized with the O_2 flush button to approximately 30 cm H_2O (Fig. 22.57). The circuit passes the leak test if it holds this pressure for at least 10 seconds. A decrease in pressure during the test should prompt a check of all plug-in, push-fit, and screw connectors, the seal of the absorber canister, and a careful inspection of the disposable tubing. One of the most common locations of a circuit leak is at the absorber canister, and it is particularly important for the anesthesia provider to apply this check rigorously immediately after the absorbent has been changed.

On many modern anesthesia machines, breathing circuit leak testing is an automated feature, although manual steps are still required for test preparation. Circuit compliance is often also automatically assessed on some machines during this phase to guide ventilator tidal volume delivery. Therefore the test should be performed with the circuit that is going to be used. The automated circuit leak test may be performed by a technician, but its completion should be verified by the provider. The importance of the leak test, on which depends the ability to deliver positive pressure ventilation, implies that it must be the provider's responsibility.

The APL valve should also be assessed at this time by opening it widely after the pressure test and ensuring that the breathing circuit pressure decreases rapidly to zero. A prompt pressure drop should occur regardless of APL valve design. The ability of the pressure-limiting type APL valve to maintain stable circuit pressure can be easily assessed, if required, by setting the APL valve to 30 cm H_2O, occluding the patient's Y-piece in a manual mode of ventilation, increasing gas flow to approximately 5 L/min, and ensuring the circuit pressure, once stable, remains within a range close to that set on the APL valve.

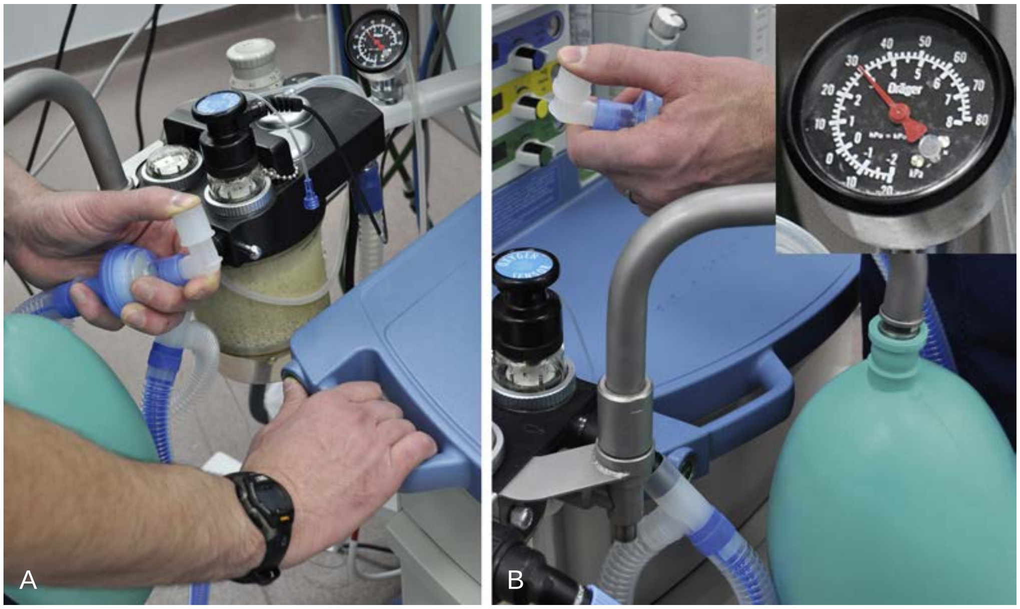

Fig. 22.57 Manual breathing system pressure and leak testing. Breathing system pressure and leak testing should be performed with the circuit configuration that will be used during anesthetic delivery. (A) The patient Y-piece or elbow is occluded, and the oxygen flush button is used to pressurize the breathing circuit to approximately 30 cm H_2O. (B) The circuit should hold pressure at this level for at least 10 seconds. It is important to ensure that the gas flows are set to zero (or their minimal values), the gas sample line is removed, and its circuit port is occluded.

Item 13: Verify That Gas Flows Properly Through the Breathing Circuit During Both Inspiration and Exhalation

Frequency: Before each use
Responsible parties: Provider and technician

This item assesses the circle breathing system for unobstructed flow and proper function of the unidirectional valves. This test of circuit flow is easily accomplished by placing a "test lung" or an extra breathing bag at the patient Y-piece. In the "bag" or a manual mode of ventilation, the operator ventilates the artificial "lung" with the breathing bag, then actively "exhales" (squeezes) the test lung back to the breathing bag in a to-and-fro motion (Fig. 22.58). This is the so-called *flow test*. The inspiratory valve should open and the expiratory valve should close during inspiration, and vice versa for exhalation. Obstruction to inspiratory flow during the flow test manifests as a "tight" breathing bag on "inspiration," whereas expiratory limb obstructions cause impeded "exhalation." Some form of flow test should be conducted because leak testing does not reliably identify circuit obstruction or unidirectional valve malfunction. Undetected circuit obstructions are particularly ominous and can manifest dramatically and sometimes immediately following induction.[147,148,150] Subtle circuit obstruction may not be appreciable except by capnometry.

Automated machine checks may not assess for (or detect) obstruction to flow within the breathing circuit. A number of complications and near-misses involving an obstructed breathing circuit have been reported despite the performance of the automated circuit check.[9,231,234b,234c] Although most user's manuals for machines that perform automated aspects of the pre-use checkout describe a leak test function, few specifically describe a flow test or an assessment of unidirectional valve function. In fact, some modern machines that incorporate automated checkout steps, including a leak test, recommend a manual assessment of the inspiratory and expiratory valves.[214,31a] In the experience of this chapter's authors, a full checkout procedure with test lung is uncommon in this era of automated machine checks. If this test is omitted, providers must be cognizant of the fact that unidirectional valve malfunction and breathing circuit obstruction have not been ruled out before starting the case.

Item 14: Document Completion of Checkout Procedures

Responsible parties: Provider and technician

Documentation of completion of the anesthetic checkout procedure by *providers* should occur within the anesthetic record. Currently, no guidance is available regarding where anesthesia or biomedical technician documentation of checkout procedures should occur. However, it would be prudent to maintain a detailed departmental log as a quality assurance tool.

Item 15: Confirm Ventilator Settings and Evaluate Readiness to Deliver Anesthesia Care (Anesthesia Time Out)

Frequency: Immediately before initiating the anesthetic regimen
Responsible parties: Provider

The authors of the 2008 *Recommendations* include as the last step in the PAC an "anesthesia time out." The time out asks the anesthesia provider to confirm 6 items:

- Monitors functional?
- Capnogram present?
- Oxygen saturation by pulse oximetry measured?
- Flowmeter and ventilator settings proper?
- Manual/ventilator switch set to manual?
- Vaporizer(s) adequately filled?[11b]

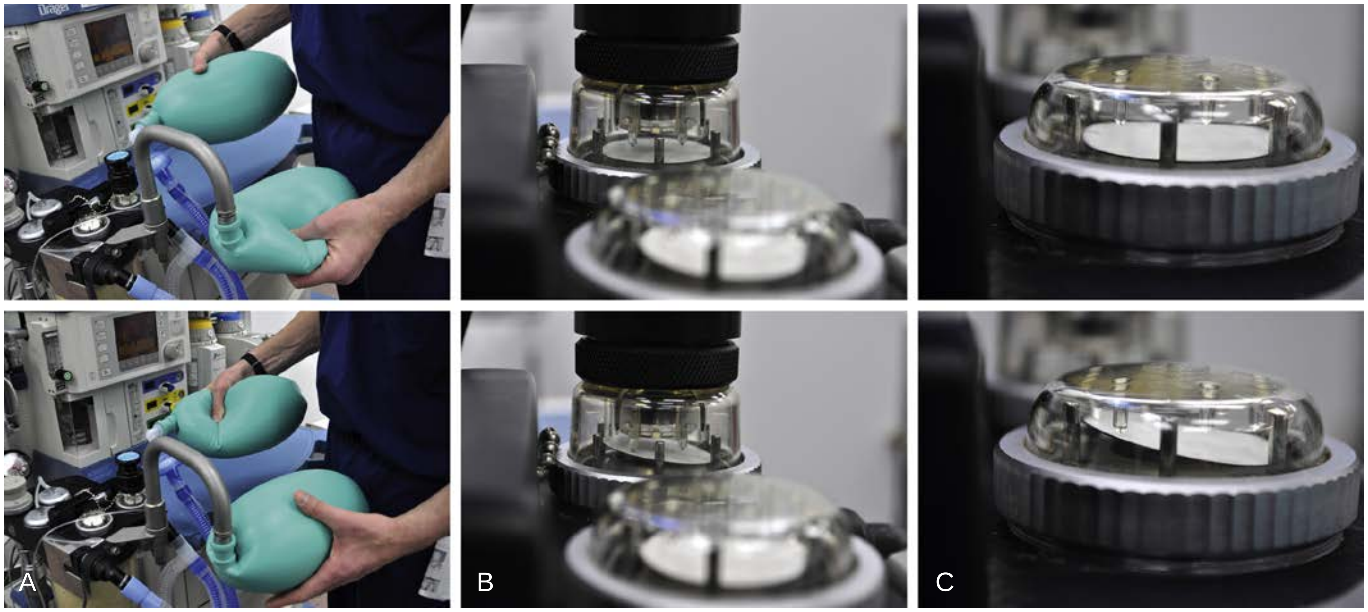

Fig. 22.58 (A–C) Verification that gas flows properly through the breathing circuit during both inspiration and exhalation with the to-and-fro "flow test." Top row, A test lung or second reservoir bag is placed on the patient elbow piece. A squeeze of the breathing bag should cause flow through the inspiratory limb, open the inspiratory valve, fill the test lung, and hold the expiratory valve closed. Bottom row, A reciprocal squeeze of the test lung should cause flow through the expiratory limb, open the expiratory valve, fill the breathing bag, and hold the inspiratory valve closed. Circuit flow during the test should be smooth and unimpeded.

This last step serves as a recommended final preinduction check list of the machine and other important items including the application of essential monitors. Verifying appropriate ventilator settings is an important safety check, especially in practices with mixed adult and pediatric cases. Many contemporary anesthesia workstations can be programmed to offer adult and pediatric "profiles" that adjust the anesthesia ventilator's default tidal volume and respiratory rate. Some older machines are more likely to retain the previous patient's settings, with the potential for under- or over-ventilation. Spending time adjusting ventilator settings in the immediate postinduction period can be distracting.

The checklist above focuses on the anesthesia workstation but does not include other key equipment such as medications, intubation supplies, monitoring transducers, etc. Some providers rely on final check mnemonic devices such as the MS MAIDS checklist (Box 22.5). Regardless of the specific steps, a final checklist that verifies the presence and function of key safety items is fundamental to the safe delivery of anesthesia.

BOX 22.5 The MS MAIDS Checklist*

- **Machine:** The machine checkout is complete; the vaporizers are filled, closed, and set to "0"; all gas flows knobs are set to zero flow; the ventilator and pressure settings are appropriate for the upcoming patient, with the machine in manual/spontaneous breathing mode, and the adjustable pressure-limiting valve is open.
- **Suction:** Patient suction is adequate to clear the airway.
- **Monitors:** All required standard monitors are present and ready to go.
- **Airway:** Primary airway equipment and appropriate backup equipment are ready to go.
- **Intravenous:** Intravenous lines, fluids, and associated equipment are ready to go.
- **Drugs:** All necessary medications are available and are properly labeled.
- **Special:** Any special or unique items (i.e., additional monitors) required for the case are available and ready.

*An example mnemonic for an "Anesthesia Time Out," which ensures that all appropriate checks have been completed, all essential equipment is available, and the machine is properly configured for the next patient.

Additional Comments Pertaining to the ASA's Pre-Anesthesia Checkout Procedure Recommendations (2008)

Although the 2008 PAC procedures are comprehensive, several steps that were part of the earlier PAC recommendations[228,235] did not appear in the current recommendations. Some of these are still found in machine user's manuals. The use of these steps should be based on local needs or requirements because the 2008 recommendations are not restrictive nor intended to be limiting. Some of these items are:

1. Disconnecting the central oxygen supply line to assess the low–oxygen supply pressure alarm and to purge the tank pressure gauges to zero
2. Inspecting the gas supply hoses for cracks or wear
3. Testing the flowmeters for smooth operation
4. Testing the proportioning system by attempting to create a hypoxic oxygen–nitrous oxide mixture

AUTOMATED ANESTHESIA MACHINE CHECKOUT PROCEDURES

Important points to consider regarding automated PAC features or "self-tests" are that (1) they differ between manufacturers and models; (2) it is sometimes difficult to determine precisely which segments or components are actually being checked by reading the user's manual, and (3) *no* machine automatically checks all the items on an effective PAC. At least some manual steps are required. Investigators have suggested that many providers do not understand exactly what is being checked by automated checks, or they make false assumptions regarding their respective machine's automated checkout procedure. It is easy to understand why the authors of the ASA's 2008 *Recommendations for Pre-Anesthesia Checkout Procedures* warned about an overreliance on the automated machine checkout. For example, one manufacturer's self-test screen reports a "leakage" amount, but the display or manual does not specify which section is responsible (e.g., the breathing circuit or the LPS). The operator must make an assumption that the low-pressure system is also being tested for leaks, and the manual does not state that any vaporizer should be turned "on" during leak testing. Finally, it was not clear in this manual whether the circuit is assessed for proper unidirectional flow or obstruction. When developing a local PAC procedure, providers should gain familiarity with their machine's automated checkout procedure through the user's manual. If an important item is not actually part of the described self-check or is not suggested in the user's manual, it should not be assumed that it can be neglected. Not requiring that conventional vaporizers be opened during a leak test of the low-pressure system is such an example.

MACHINE-EMBEDDED PREANESTHESIA MACHINE CHECKOUT CHECKLISTS

Some anesthesia machines have embedded PAC checklists, which are displayed during machine checkout. Like their paper counterparts, they help guide users through manual and self-test functions. If an embedded checklist provides a complete solution for a department, then it can be used exclusively. However, local requirements may exceed or depart from the embedded checklist. In these cases, the use of the embedded checklist (or a modification thereof) can become a line item within the local PAC checklist.

DEVELOPING A LOCAL PREANESTHESIA MACHINE CHECKOUT CHECKLIST

The goal of a PAC is to evaluate and configure the anesthesia workstation properly so it performs its functions safely and smoothly. The objectives of the PAC *checklist* are to guide the operator through an effective PAC and to promote compliance through ease of use. A PAC checklist can also serve as a quality control tool by codifying important items onto an organized list used by all providers.[236] The checkout procedure should be ergonomically ordered to minimize redundant movements and save time by placing procedures in a rational sequence.[237] Finally, the checklist should be as short as possible, yet be detailed enough so critical items are not omitted.

Acknowledgment

The editors and publisher would like to thank Drs. Steven G. Venticinque and J. Jeffrey Andrews for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

23 Intravenous Anesthetics

JAAP VUYK, ELSKE SITSEN, and MARIJE REEKERS

KEY POINTS

- The introduction of thiopental into clinical practice in 1934 marked the beginning of modern intravenous (IV) anesthesia. Today, IV anesthetics are used for induction and maintenance of anesthesia and sedation in a wide variety of circumstances.
- The most commonly used IV anesthetic is propofol, an alkylphenol presently formulated in a lipid emulsion. Propofol provides rapid onset and offset with context-sensitive decrement times of approximately 10 minutes when infused for less than 3 hours and less than 40 minutes when infused for up to 8 hours. Its mechanism of action is likely the enhancement of gamma-aminobutyric acid (GABA)-induced chloride currents. Propofol causes a dose-dependent decrease in arterial blood pressure predominantly through a decrease in systemic vascular resistance and causes moderate respiratory depression. A unique action of propofol is its antiemetic effect, even at concentrations less than those producing sedation. A growing body of evidence suggests propofol may have antitumor potential.
- Barbiturates were the most commonly used IV drugs administered to induce anesthesia prior to the introduction of propofol. Thiopental provides rapid onset and offset when used as a single dose, but it accumulates rapidly with repeated or prolonged administration thus postponing recovery from anesthesia. Methohexital has a rapid onset and offset similar to propofol for procedures lasting less than 2 hours. The barbiturates are administered as sodium salts diluted in a water base at an alkaline pH. Similar to propofol, the barbiturates provide their hypnotic effects largely through action on the GABAA receptor. Barbiturates provide cerebral protection and are, apart from induction of anesthesia, used primarily for this purpose. They cause a moderate dose-dependent decrease in arterial blood pressure (primarily as a result of peripheral vasodilation) and respiratory drive. The barbiturates are contraindicated in patients with porphyria.
- The benzodiazepines are used primarily for anxiolysis and amnesia or for conscious sedation. The water-soluble benzodiazepine midazolam is most frequently used intravenously because of its rapid onset and offset compared with other benzodiazepines (e.g., diazepam). The onset time of midazolam is slower than that of propofol and barbiturates, and its offset, especially with larger doses or a prolonged infusion, is considerably longer than that of propofol or methohexital and may be prolonged in hepatic and renal failure. The benzodiazepines act through the GABA receptor. Flumazenil is a specific benzodiazepine antagonist. It can be used to reverse the effects of benzodiazepines but should be used with caution because its antagonizing effect often lasts shorter than the benzodiazepine effect that it is supposed to antagonize. The benzodiazepines generally produce only a mild decrease in arterial blood pressure and mild-to-moderate respiratory depression. Remimazolam is the most recent benzodiazepine with an ultrashort duration of action due to its rapid clearance through plasma esterases.
- Ketamine is a phencyclidine derivative that acts primarily, but not entirely, as antagonist of the N-methyl-D-aspartate (NMDA) receptor. It produces a dissociative state of hypnosis and analgesia. It has been used for induction and maintenance of anesthesia. Ketamine is associated with significant adverse psychological effects from larger doses and has several other side effects. It is used now primarily for its analgesic properties. It has rapid onset and relatively rapid offset, even after an infusion of several hours. It has sympathomimetic effects that preserve cardiac function. Ketamine has minimal effect on respiration and tends to preserve autonomic reflexes. In addition, ongoing research suggests ketamine may play a role as an antidepressant.
- Etomidate is an imidazole derivative used primarily for induction of anesthesia, especially in elderly patients and patients who are cardiovascularly compromised. It has a rapid onset of effect and a rapid offset even after a continuous infusion. A dose used to induce anesthesia results in inhibition of adrenocortical synthesis and possible mortality in intensive care unit (ICU) patients. The major advantage of etomidate is its minimal effect on the cardiovascular and respiratory systems.
- Dexmedetomidine is the most recently released IV anesthetic. It is a highly selective α_2-adrenergic agonist that produces sedation, sympatholysis, hypnosis, and analgesia. Dexmedetomidine is approved for ICU sedation of initially intubated and mechanically ventilated patients, up to 24 hours. It may be advantageous for its ability to prevent delirium. Its second indication is procedural sedation of nonintubated patients. With increasing frequency dexmedetomine finds its use as a sedative during invasive or radiological procedures and as an adjunct in central or peripheral neural blockade. Its primary action is as an agonist on α_2-receptors in the locus caeruleus. It has minimal effect on respiration. Heart rate and cardiac output show a concentration-dependent decrease.

- Droperidol, a butyrophenone and major tranquilizer, was initially used to produce a state of neuroleptanesthesia. Its prolongation of the QT interval has resulted in its withdrawal in several countries and its limitation to the treatment of postoperative nausea and vomiting (PONV) with a black box warning in the United States. Because the use of low-dose droperidol (<1.25 mg) for PONV has not been approved by the US Food and Drug Administration (FDA), the black box warning does not relate to this use. Clinically significant prolongation of the QT interval by doses used for PONV (0.625 to 1.25 mg) has been challenged by several editorials, and this effect has not been substantiated by review of the reported cases or other literature. Low-dose droperidol remains an effective antiemetic therapy and is used as such in many European countries (also see Chapter 80).

Intravenous (IV) anesthesia can be traced back to 1656 with Percival Christopher Wren's and Daniel Johann Major's first experiments with the IV using a goose quill and bladder to inject wine and ale into a dog's vein. In 1665 German naturalist and physician Sigismund Elsholz made the first attempt at IV anesthesia in humans and investigated the possibilities of IV injection with opiates. IV anesthesia further evolved when Fedoroff started using hedonal in St. Petersburg in 1905 and entered the era of modern anesthesia with the release of thiopental in 1936.[1] Since these beginnings, and in particular during the past three decades, the pharmacokinetics and pharmacodynamics of IV anesthetics and their interactions have been described in increasingly greater detail. This body of knowledge and the availability of increasingly shorter-acting drugs now allow the anesthesia provider to administer anesthesia not on the basis of the needs of the population but to focus anesthesia on the individual needs of the patient. Today's anesthesia provider is supported by modern IV drug administration techniques like target-controlled infusion and central nervous system (CNS) monitoring devices to further optimize and individualize the application of IV anesthesia. This chapter describes the current status of the pharmacology of IV anesthetics and their place in modern anesthesia.

Propofol

HISTORY

Since its introduction in the 1970s, propofol has become the most used IV hypnotic today. Building on work on the sedative properties of phenol derivates in mice, propofol was developed in the United Kingdom by Imperial Chemical Industries as ICI 35868. The initial solution of propofol, as released in 1977 in Cremophor EL,[2] was withdrawn because of anaphylactic reactions, and replaced and reformulated as an emulsion of a soya oil/propofol mixture in water and relaunched in 1986. Propofol is used for induction and maintenance of anesthesia and for sedation in and outside the operating room.

PHYSICOCHEMICAL CHARACTERISTICS

Propofol (Fig. 23.1) is one of a group of alkylphenols that were explored for their hypnotic properties in animals.[3-5] The alkylphenols are highly lipid soluble and are insoluble in an aqueous solution.[6] Numerous formulations of propofol are marketed today. The formulation most used is that of 1% propofol, 10% soybean oil, and 1.2% purified egg phospholipid added as emulsifier, with 2.25% of glycerol as a tonicity-adjusting agent, and sodium hydroxide to change the pH. Following concerns regarding microbial growth in the emulsion, EDTA was added for its bacteriostatic activities. Propofol has a pH of 7 and appears as a slightly viscous, milky white substance, a result of small lipid droplets in solution. In Europe, a 2% formulation and a formulation in which the emulsion contains a mixture of medium-chain and long-chain triglycerides also are available. All formulations commercially available are stable at room temperature, are not light sensitive, and may be diluted with 5% dextrose in water. Propofol concentrations may be measured both in whole blood and in the exhaled air.[7-10]

In December 2008 the US Food and Drug Administration (FDA) approved fospropofol disodium (Lusedra) for monitored anesthesia care in adult patients undergoing diagnostic and therapeutic procedures. Fospropofol is a water-soluble prodrug of propofol that is metabolized by alkaline phosphatases in the liver to the active metabolite propofol. One millimole (mmol) of propofol is generated for each mmol of fospropofol sodium administered. About 1.86 mg of fospropofol sodium is the molar equivalent of 1 mg propofol. In April 2010, six studies on the pharmacokinetics and pharmacodynamics of fospropofol were retracted as a result of an analytical assay inaccuracy that was discovered after publication of these studies.[11,12] Since then, few data on the pharmacokinetics and pharmacodynamics of fospropofol have been published. Although fospropofol remains available for monitored anesthesia care, data now available are scarce and most pharmacokinetic-pharmacodynamic data that are available come from the United States as described in a recent review.[13] In contrast to propofol, fospropofol is not associated with pain on injection, although mild to moderate perineal paresthesias and pruritis minutes after a bolus injection of fospropofol have been reported and may be due to a phosphate metabolite.

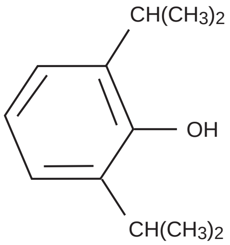

Fig. 23.1 Structure of propofol, an alkylphenol derivative.

PHARMACOKINETICS

Propofol is oxidized to 1,4-diisopropyl quinol in the liver. Propofol and 1,4-diisopropyl quinol are conjugated with glucuronic acid to propofol-1-glucuronide, quinol-1-glucuronide, and quinol-4-glucuronide, which then may be excreted by the kidneys.[14,15] After a 2.5-hour anesthetic with propofol, patients excrete propofol and propofol metabolites for over 60 hours.[15] Less than 1% propofol is excreted unchanged in urine, and only 2% is excreted in feces. The metabolites of propofol are thought to be inactive. Because clearance of propofol (>1.5 L/min) exceeds hepatic blood flow, extrahepatic metabolism or extrarenal elimination may occur. Extrahepatic metabolism has been confirmed during the anhepatic phase of patients receiving a transplanted liver with the determination of propofol metabolites after propofol administration in the absence of liver tissue. The most important extrahepatic site for propofol metabolism is the kidney.[16,17] Renal metabolism of propofol accounts for up to 30% of propofol clearance, which explains the rapid clearance of propofol, which exceeds liver blood flow. The lungs also may play a role in the extrahepatic propofol metabolism.[18,19] In sheep, the lungs are responsible for approximately 30% of the uptake and first-pass elimination after a bolus dose. In humans, a 20% to 30% decrease in propofol concentration measured across the lung exists with a higher concentration of the metabolite 2,6-diisopropyl 1,4-quinol on the arterial side of the circulation.

Propofol is generally known for its hemodynamic depressant effects and may reduce hepatic blood flow. As such, it may reduce the clearance of other drugs metabolized by the liver, in particular those with a high extraction ratio.[20] In addition, propofol is known as a CYP3A4 inhibitor.[21] In contrast to enzyme induction that may take several days or weeks to develop, competitive inhibition of CYP activity may occur almost instantaneously due to the competition of two drugs (e.g., propofol and midazolam) for the enzyme's active site. A short-term exposure to propofol at a blood concentration of 3 μg/mL already reduces the CYP3A4 activity by about 37%.

Fospropofol[22-28,28a] is a water-soluble prodrug of propofol and is chemically described as phosphono-*O*-methyl-2, 6-diisopropylphenol, disodium salt ($C_{13}H_{19}O_5PNa_2$). Fospropofol is metabolized by alkaline phosphatases to propofol, formaldehyde, and phosphate. Formaldehyde is further metabolized to formate which is then eliminated, primarily by oxidation to carbon dioxide. Over 71% of fospropofol is recovered in the urine within 192 hours following a single 400 mg IV dose. Renal elimination is <0.02% and total body clearance in the order of 0.28 L/h/kg. The terminal elimination half-life of fospropofol is 0.88 hours. The pharmacokinetics of fospropofol and liberated propofol are not affected by race, sex, or mild to moderate renal impairment. Furthermore, fospropofol pharmacokinetics are not affected by age or alkaline phosphatase concentration. So far, no pharmacokinetic interactions have been found between fospropofol and fentanyl, midazolam, morphine, or with propofol. This is probably because fospropofol is not subject to cytochrome P450 enzyme mediated metabolism.[13]

The pharmacokinetics of propofol have been described by two-compartment and three-compartment models (Table 23.1).[28b] After a single bolus dose, whole blood propofol levels decrease rapidly as a result of redistribution and elimination (Fig. 23.2). The initial distribution half-life of propofol is 2 to 8 minutes. Studies in which the disposition of propofol is described by a three-compartment model give initial and slow distribution half-lives of 1 to 8 minutes and 30 to 70 minutes and an elimination half-life of 4 to 23.5 hours.[29-34] The context-sensitive half-time for propofol (Fig. 23.3) for infusions of up to 8 hours is less than 40 minutes.[35] Because the required decrease in concentration for awakening after anesthesia or sedation with propofol is generally less than 50%, recovery from propofol remains rapid even after prolonged infusion. The volume of distribution of the central compartment has been calculated between 6 and 40 L, and the volume of distribution at steady state has been calculated as 150 to 700 L. The

TABLE 23.1 Pharmacokinetic Variables for Commonly Used Intravenous Anesthetics

Elimination	Elimination Half-Life (h)	Clearance (mL/kg/min)	Vd_{SS} (L/kg)
Dexmedetomidine	2-3	10-30	2-3
Diazepam	20-50	0.2-0.5	0.7-1.7
Droperidol	1.7-2.2	14	2
Etomidate	2.9-5.3	18-25	2.5-4.5
Flumazenil	0.7-1.3	5-20	0.6-1.6
Ketamine	2.5-2.8	12-17	3.1
Lorazepam	11-22	0.8-1.8	0.8-1.3
Methohexital	2-6	10-15	1.5-3
Midazolam	1.7-2.6	6.4-11	1.1-1.7
Propofol	4-7	20-30	2-10
Thiopental	7-17	3-4	1.5-3

From Reves JG, Glass P, Lubarsky DA, et al. Intravenous anesthetics. In: Miller RD, Eriksson LI, Fleischer LA, et al, eds. *Miller's Anesthesia,* 7th ed. Philadelphia: Churchill Livingstone; 2010: 719–768.

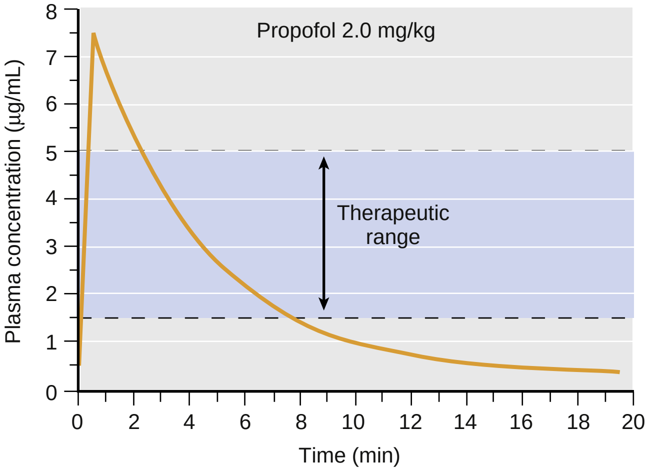

Fig. 23.2 Simulated time course of whole blood levels of propofol after an induction dose of 2 mg/kg. Blood levels required for anesthesia during surgery are 2 to 5 μg/mL, with awakening usually occurring at a blood level less than 1.5 μg/mL.

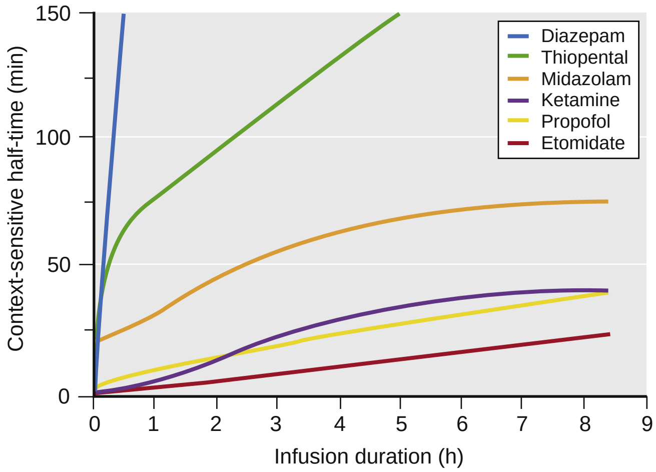

Fig. 23.3 The context-sensitive half-times for commonly used IV anesthetic drugs. The context-sensitive half-time is the time for the plasma level of the drug to decrease 50% after cessation of infusion. The duration of infusion is plotted on the horizontal axis. The rapidity with which the drug level decreases is directly related to the time of infusion (i.e., the longer the drug is infused, the longer the half-time). Etomidate, propofol, and ketamine have significantly shorter half-times than thiopental and diazepam, which makes them more suitable for prolonged infusion.

central compartment generally is smaller in the elderly as a result of the reduced cardiac output in these patients. A reduced cardiac output is associated with a higher peak plasma concentration, which is reflected by a smaller central compartment in the pharmacokinetic analysis. The clearance of propofol is extremely high—1.5 to 2.2 L/min. As discussed earlier, this exceeds hepatic blood flow, and extrahepatic metabolism has been shown.

The equilibrium constant for propofol based on suppression of the activity in the electroencephalogram (EEG) is about 0.3 min, and the half-life of equilibrium ($T½_{ke0}$) between plasma concentration and EEG effect is 2.5 minutes. The time to peak effect is 90 to 100 seconds. The onset of EEG effect with propofol seems to be independent of age. The onset of decreasing arterial blood pressure is much slower (double the time) and increases with age.[36] For EEG and blood pressure changes, elderly patients show a concentration dependent increasing sensitivity. The pharmacokinetics of propofol may be altered by various factors (e.g., gender, weight, preexisting disease, age, and concomitant medication).[37-39] Some studies suggest that propofol may exhibit nonlinear pharmacokinetics.[40] Because propofol has a high extraction ratio, this may impair its own clearance by decreasing cardiac output and thus hepatic blood flow.[41] As a result, a doubling of the dose of propofol may lead to a drug concentration that may be more than twice that initially experienced. In contrast, an increase in cardiac output induced by sympaticomimetic administration may lead to a decrease in the propofol plasma concentration. In a hemorrhagic shock model propofol concentrations increased 20% until uncompensated shock occurred, when there was a rapid and marked increase in propofol concentrations.[42]

In term and preterm neonates, variability of propofol clearance was accounted for largely by postmenstrual and postnatal age with very fast maturation of clearance in neonatal life. Dosing in these neonates needs to be calculated with extreme care.[43,44] Women have a larger volume of distribution and higher clearance rates, but the elimination half-life is similar for males and females. Elderly individuals have decreased clearance rates and a smaller central compartment volume.[45] Both may be the result of a reduced cardiac output. Because of this and because of an increased sensitivity to the propofol effect in the elderly, patients aged 80 years or older generally need 50% of the propofol dose of patients aged 20 years old to target the same level of sedation or hypnosis.[29,38,45,46] Children have a relatively larger central compartment volume (50%) and a more rapid clearance (25%).[31,47] In children older than 3 years, volumes and clearances should be weight adjusted (also see Chapter 77). Children younger than 3 years of age also show weight-proportional pharmacokinetic parameters, but with larger central compartment and systemic clearance values than in adults or older children. This finding explains the larger dose requirements in this age group.[48,49] Hepatic disease seems to result in larger steady state and central compartment volumes; clearance is unchanged, but the elimination half-life is slightly prolonged, as is time to recovery.[50,51] In clinical practice, no significant dose adjustment is required in case of hepatic disease. The extrahepatic clearance of propofol that may compensate for a reduced hepatic function may be responsible for this.

Midazolam affects the pharmacokinetics of propofol.[52] In the presence of a sedative midazolam concentration of 200 ng/mL, the blood propofol concentrations become elevated by about 25%. Midazolam reduces propofol metabolic clearance from 1.94 to 1.61 L/min, Cl_2 from 2.86 to 1.52 L/min, and Cl_3 from 0.95 to 0.73 L/min. The high extraction ratio of propofol of 0.79 to 0.92 suggests that the metabolic clearance of propofol may not be affected by enzyme inhibition but may be susceptible to changes in hepatic perfusion. The changes in the pharmacokinetics of propofol induced by midazolam thus may be the result of the hemodynamic alterations induced by the coadministration of midazolam.

Propofol in its turn affects midazolam pharmacokinetics as well.[20] In the presence of sedative concentrations of propofol, plasma midazolam concentrations increased by 27%. In the presence of propofol, midazolam is administered in a smaller central compartment from which midazolam is cleared and distributed less rapidly to peripheral tissues. For example, alfentanil[53] has been shown to increase blood propofol concentrations through a reduction in the elimination and distribution clearance of propofol. This is in line with other pharmacokinetic interactions between hypnotics and opioids when combined with propofol. Propofol has been shown to increase alfentanil concentrations by decreasing the elimination and the rapid and slow distribution clearances of alfentanil. Coadministration of propofol increased remifentanil concentrations via both a decrease in the central volume of distribution and distributional clearance of remifentanil by 41% and elimination clearance by 15%. Propofol kinetics is unaltered by renal disease.

As previously stated, pharmacokinetic data on the disposition of fospropofol are scarce. Phase I and phase II studies were conducted in Europe when a detection error became apparent resulting in the retraction of six published manuscripts. Currently, no further pharmacokinetic studies have been initiated. The pharmacokinetics of fospropofol in humans remains largely unknown.

Fospropofol protein binding is extensive (98%).[13] It has a small volume of distribution of 0.3 L/kg, a total body clearance of 0.36 L/kg/h with a terminal elimination half-life of 0.88 hours. After a bolus dose of 6 mg/kg of fospropofol, the parent drug peaks at 4 minutes and is rapidly metabolized to propofol with a peak plasma propofol concentration at 12 minutes after administration of fospropofol. With this fospropofol dose the highest plasma concentration reached (Cmax) of fospropofol was 78.7 μg/mL and the Cmax of propofol was 1.08 μg/mL. The total body clearance of fospropofol and propofol were 0.36 and 3.2 L/kg/h. The terminal half-lives were 0.88 and 1.13 hours, respectively.

Pharmacodynamics

EFFECTS ON THE CENTRAL NERVOUS SYSTEM

The hypnotic action of propofol is mostly mediated by enhancing γ-aminobutyric acid (GABA)-induced chloride current through its binding to the β-subunit of $GABA_A$ receptor. Sites on the β_1-subunit, β_2-subunit, and β_3-subunit of the transmembrane domains are crucial for the hypnotic action of propofol.[54,55] The α-subunit and γ_2-subunit subtypes also seem to contribute to modulating the effects of propofol on the GABA receptor. The effect of propofol has been described in two manners—indirect and direct. Propofol exhibits an indirect effect by potentiation of the ion channel activation by GABA, shifting the concentration-response relationship to the left. At higher propofol concentrations, propofol is also thought to directly activate $GABA_A$ receptor channels.[56-58] The exact mechanism and location of changes that are associated with the change from consciousness to the unconscious state are not yet fully understood. Some experts suggest that a proper functioning of the brain stem-thalamo-cortical arousal circuits are critical while others state that consciousness is more related to fronto-parietal association cortex activity. Propofol, through its action on $GABA_A$ receptors[59] in the hippocampus, inhibits acetylcholine release in the hippocampus and prefrontal cortex. The α_2-adrenoreceptor system also seems to play an indirect role in the sedative effects of propofol.[60] Resting state fMRI studies suggest that propofol's action may be related to a CNS that reduces its discriminable state and switches into stereotypic patterns of firing under propofol sedation.[61] The so called default mode network (DMN), including the posterior cingulated, the medial frontal cortex, and bilateral parietal cortices, is the anatomical substrate in which these stereotypical patterns become visible. Using positron emission tomography, propofol hypnosis is related with reduced activity in the thalamic and precuneus regions. These regions likely play an important role in propofol-induced unconsciousness.[62]

Propofol results also in widespread inhibition of the *N*-methyl-d-aspartate (NMDA) subtype of glutamate receptor through modulation of sodium channel gating, an action that also may contribute to the drug's CNS effects.[63,64] Propofol has a direct depressant effect on neurons of the spinal cord. In acutely dissociated spinal dorsal horn neurons, propofol acts on $GABA_A$ and glycine receptors.[65] The sense of well-being in patients with propofol is related to the increase in dopamine concentrations in the nucleus accumbens (a phenomenon noted with drugs of abuse and pleasure-seeking behavior).[66] Propofol's antiemetic action may be explained by the decrease in serotonin levels it produces in the area postrema, probably through its action on GABA receptors.[67]

The onset of hypnosis after a dose of 2.5 mg/kg is rapid (one arm–brain circulation), with a peak effect seen at 90 to 100 seconds. The median effective dose (ED_{50}) of propofol for loss of consciousness is 1 to 1.5 mg/kg after a bolus. The duration of hypnosis is dose-dependent, being 5 to 10 minutes after 2 to 2.5 mg/kg. Age markedly affects the induction dose, which is largest at ages younger than 2 years (ED_{95} 2.88 mg/kg) and decreases with increasing age. This is a direct result of the altered pharmacokinetics in children and elderly. Children exhibit a relatively larger central compartment and therefore need a higher dose to assure a similar blood-drug concentration.[68-70] In addition, the rapid clearance of propofol in children requires a larger maintenance dose as well. Increasing age decreases the propofol concentration required for loss of consciousness.

At subhypnotic doses, propofol provides sedation and amnesia. Propofol infusions of at least 2 mg/kg/h were necessary to provide amnesia in unstimulated volunteers. Awareness during surgery at higher infusion rates has been reported. During surgical procedures, extremely high infusion rates producing blood propofol concentrations in excess of 10 μg/mL may be necessary to prevent awareness if propofol is used as the sole anesthetic. Propofol also tends to produce a general state of well-being. Hallucinations, sexual fantasies, and opisthotonos occur after propofol administration.

The effect of propofol on the EEG, as assessed after 2.5 mg/kg followed by an infusion, shows an initial increase in alpha rhythm followed by a shift to gamma and theta frequency. Rapid infusion rates produce burst suppression at blood propofol concentrations higher than 8 μg/mL. Propofol causes a concentration-dependent decrease in the bispectral index (BIS), with 50% and 95% of patients unable to respond to a verbal command at a BIS of 63 and 51, respectively. The propofol concentration at which 50% of volunteers failed to respond to verbal command was 2.35 μg/mL. Lack of recall was observed in 95% of patients at a BIS value of 77.[71] Propofol effect site concentrations provide similar correlation with decreases in the spectral entropy variable derived from the EEG as it does with BIS, and a similar ability to titrate propofol anesthetic effect. The effect of propofol on epileptogenic EEG activity is controversial. Propofol may suppress seizure activity via GABA agonism, inhibition of NMDA receptors, and modulation of slow calcium ion channels. However, the same GABA agonism and glycine antagonism may also induce clinical seizures and EEG epileptiform changes.[72] This especially may occur during induction of and emergence from anesthesia. Propofol has a dose-dependent anticonvulsant. Propofol has even been used to treat epileptic seizures. Yet propofol can cause grand mal seizures and has been used for cortical mapping of epileptogenic foci.[73]

Unfortunately, propofol can be addictive. An important issue in the potential of abuse is the development of tolerance. Tolerance to a drug creates circumstances for abuse. Propofol is being used as a sedative in the intensive care unit (ICU); in 20% to 40% of patients, the propofol dosage regimen needs to be repeatedly adjusted upward in order to maintain the same effect.[74] Data on propofol abuse in the general public are unknown but the incidence of abuse is likely to be low compared to other substances. For healthcare workers, propofol is easy to access and case reports of lethal self-administration do occur. Some have suggested that there are more frequent incidences of propofol abuse by healthcare providers[75,76] and support stricter propofol regulation. In contrast to propofol, fospropofol was classified in 2009 by the US Drug Enforcement Administration (DEA) as a controlled substance.

Propofol decreases intracranial pressure (ICP) in patients with either normal or increased ICP (also see Chapter 57). The decrease in ICP (30% to 50%) is associated with significant decreases in cerebral perfusion pressure (CPP).[77] The use of propofol in head-injured patients should be restricted to doses providing mild-to-moderate sedation (i.e., blood concentration of 2 μg/mL, infusion of 25 to 75 μg/kg/min).[78] Anesthetics are neuroprotective because they reduce the metabolic oxygen use that is beneficial for the balance between energy supply and demand and because they increase the tolerance to hypoxia by the neuronal tissue. Propofol has no direct preconditioning effect but may attenuate glutamate-mediated excitotoxicity.[79-81] Propofol acutely reduces intraocular pressure by 30% to 40%. Compared with thiopental, propofol produces a larger decrease in intraocular pressure and is more effective in preventing an increase in intraocular pressure secondary to succinylcholine and endotracheal intubation. Normal cerebral reactivity to carbon dioxide and autoregulation are maintained during a propofol infusion.

The neuroprotective effects of propofol remain controversial.[82] In an incomplete ischemia model in rats, propofol administered to burst suppression results in significantly better neurologic outcome and less brain tissue injury compared with fentanyl. Propofol administered at sedative concentrations started either immediately after or at 1 hour after an ischemic insult significantly reduced infarct size compared with awake controls infused with intralipid.[83,84] Subanesthetic doses of propofol also induce neuroapoptosis in the infant mouse brain.[85] In addition, anesthetic doses of propofol in rats[86] induce complex changes that are accompanied by cell death in the cortex and thalamus of the developing rat brain. The neuronal protective effect of propofol may be due to the attenuation of changes in adenosine triphosphate, calcium, sodium, and potassium caused by hypoxic injury and its antioxidant action by inhibiting lipid peroxidation. Current evidence indicates that propofol can protect neurons against ischemic injury caused by excitotoxicity, but neuroprotection may be sustained only if the ischemic insult is relatively mild and is not sustained after a prolonged recovery period. Prolonged propofol sedation in children is associated with adverse neurologic sequelae.[87]

Many anesthetic-related drugs decrease the required dose or blood concentrations of propofol's pharmacologic action. The "required dose" is usually directly related to the required concentration for a given effect. The propofol Cp_{50} (blood concentration needed for 50% of subjects to not respond to a defined stimulus) for loss of response to verbal command in the absence of any other drug is 2.3 to 3.5 μg/mL.[88-90] The propofol Cp_{50} to prevent movement on skin incision is 16 μg/mL; this is markedly reduced by increasing concentrations (i.e., doses) of fentanyl or alfentanil. The propofol Cp_{50} for skin incision when combined with benzodiazepine premedication (lorazepam, 1 to 2 mg) and 66% nitrous oxide is 2.5 μg/mL (venous).[91] This concentration is reduced to 1.7 μg/mL when morphine (0.15 mg/kg) rather than lorazepam is used for premedication. The concentration of propofol (when combined with 66% nitrous oxide) required during minor surgery is 1.5 to 4.5 μg/mL, and the concentration for major surgery is 2.5 to 6 μg/mL.[92] Awakening usually occurs at concentrations less than 1.6 μg/mL and orientation occurs at concentrations less than 1.2 μg/mL when the propofol concentration is decreasing. Not surprisingly, awakening is postponed in the presence of high blood concentrations of opioids. Optimal propofol blood concentrations have been defined when combined with several opioids including remifentanil, alfentanil, sufentanil, and fentanyl that assure adequate anesthesia and the most rapid return to consciousness, postoperatively (Table 23.2). In the presence of remifentanil, a relatively large-dose opioid anesthetic is recommended. Yet, with fentanyl an accompanying large dose of propofol should be used to assure rapid return to recovery postoperatively (Fig. 23.4). When equilibration between blood and effect site is allowed, however, awakening concentrations (2.2 μg/mL) are similar to concentrations associated with loss of verbal command.[93]

EFFECTS ON THE RESPIRATORY SYSTEM

Apnea occurs after administration of an induction dose of propofol; the incidence and duration of apnea depend on dose, speed of injection, and concomitant premedication.[94] An induction dose of propofol results in a 25% to 30% incidence of apnea from the respiratory depressant effects of propofol and yet a normal partial pressure of carbon dioxide in the blood ($PaCO_2$) at induction in the absence of surgical stimulation. Metabolic depression further prevents the $PaCO_2$ to increase. Yet, the duration of apnea occurring with propofol may be prolonged to more than 30 seconds. The incidence of prolonged apnea (>30 seconds) is increased further by addition of an opiate, either as premedication or just before induction of anesthesia.[92,95] A maintenance infusion of propofol (100 μg/kg/min) results in a 40% decrease in tidal volume and a 20% increase in respiratory frequency, with an unpredictable change in minute ventilation. Doubling the infusion rate from 100 to 200 μg/kg/min causes a further moderate decrease in tidal volume but no change in respiratory frequency.[96] As with other hypnotic drugs, spontaneous ventilation is the result of the respiratory depressant effects of the hypnotic agents and the decrease in CO_2 production resulting from the metabolic depression versus the stimulatory effects of the increasing $PaCO_2$ resulting from apnea and the level of nociception. Propofol (50-120 μg/kg/min) also depresses the ventilatory response to hypoxia, presumably by a direct action on carotid body chemoreceptors.[97] Propofol induces bronchodilation in patients with chronic obstructive pulmonary disease. Propofol attenuates vagal (at low concentrations) and methacholine-induced (at high concentrations) bronchoconstriction and seems to have a direct action on muscarinic receptors. Propofol inhibits the receptor-coupled signal transduction pathway through inositol phosphate

Propofol anesthesia and rational opioid selection: determination of optimal EC50-EC95 propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. *Anesthesiology*. 1997;87:1549–1562, with permission from Lippincott Williams and Wilkins©, 1997.)

generation and inhibition of Ca^{2+} mobilization. The preservative used with propofol is important regarding its bronchodilator activity. Propofol with metabisulfite (compared with propofol without metabisulfite) does not inhibit vagal or methacholine-induced bronchoconstriction. Propofol potentiates hypoxic pulmonary vasoconstriction, an effect caused by inhibition of K(+) (ATP)-mediated pulmonary vasodilatation. Propofol has an impact on the pulmonary pathophysiology of adult respiratory distress syndrome. In an animal model of septic endotoxemia, propofol (10 mg/kg/h) significantly reduced free radical mediated and cyclooxygenase catalyzed lipid peroxidation. In addition, PaO_2 and hemodynamics were maintained closer to baseline. These benefits of propofol have not yet been confirmed in humans.

EFFECTS ON THE CARDIOVASCULAR SYSTEM

The cardiovascular effects of propofol for induction and maintenance of anesthesia have been evaluated (Table 23.3).[98] The most prominent effect of propofol is a decrease in arterial blood pressure during induction of

anesthesia.[98a] Independent of the presence of cardiovascular disease, an induction dose of 2 to 2.5 mg/kg produces a 25% to 40% reduction of systolic blood pressure. Similar changes are seen in mean and diastolic blood pressure. The decrease in arterial blood pressure is associated with a decrease in cardiac output/cardiac index (±15%), stroke volume index (±20%), and systemic vascular resistance (15%-25%). Left ventricular stroke work index also is decreased (±30%). When looking specifically at right ventricular function, propofol produces a marked reduction in the slope of the right ventricular end-systolic pressure-volume relationship.

In patients with valvular heart disease, pulmonary artery and pulmonary capillary wedge pressure also are reduced, a finding that implies the resultant decrease in pressure is due to a decrease in preload and afterload. Although the decrease in systemic pressure after an induction dose of propofol is due to vasodilation, the direct myocardial depressant effects of propofol are more controversial. The decrease in cardiac output after propofol administration may be via its action on sympathetic drive to the heart. The hemodynamic response to propofol lags significantly behind that of the hypnotic effect. The effect-site equilibration half-life of propofol is in the order of 2 to 3 minutes for the hypnotic effect and about 7 minutes for the hemodynamic depressant effect.[36] This implies that hemodynamic depression increases in a few minutes after a patient has lost consciousness from an induction of anesthesia.

High concentrations of propofol abolish the inotropic effect of α- but not β-adrenoreceptor stimulation and enhance the lusitropic (relaxation) effect of β stimulation. Clinically, the myocardial depressant effect and the vasodilation are dose-dependent and plasma concentration-dependent.[99] Propofol is a vasodilator due to a reduction in sympathetic activity. The mechanism of this activity is a combination of a direct effect on intracellular smooth muscle calcium mobilization, inhibition of prostacyclin synthesis in endothelial cells, reduction in angiotensin II–elicited calcium entry,[100,101] activation of K adenosine triphosphate channels, and stimulation of nitric oxide. The stimulation of nitric oxide may be modulated by any intralipid rather than propofol itself.

Heart rate does not change significantly after an induction dose of propofol. Propofol either may reset or may inhibit the baroreflex, reducing the tachycardic response to hypotension. Propofol also decreases cardiac parasympathetic tone in a dose-dependent manner. Propofol has a minimal direct effect on sinoatrial node function or on normal atrioventricular and accessory pathway conduction. Propofol attenuates the heart rate response to atropine in a dose-dependent manner. Propofol suppresses atrial (supraventricular) tachycardias and probably should be avoided during electrophysiologic studies. The peak plasma concentrations obtained after a bolus dose are substantially higher than the concentrations seen with a continuous infusion and may reach concentrations up to 80 to 100 μg/mL. Because the vasodilatory and myocardial depressant effects are concentration-dependent, the decrease in arterial blood pressure from propofol during the infusion phase (maintenance of anesthesia) is much less than that seen after induction of anesthesia by an intravenous bolus administration of propofol. An infusion of propofol reduces myocardial blood flow and oxygen consumption. Thus, global myocardial oxygen supply-to-demand ratio is likely preserved. The cardioprotective effect of propofol versus volatile anesthetics in patients having cardiac surgery on- or off-cardiopulmonary bypass is less debatable. In two large studies comparing propofol with sevoflurane in patients undergoing cardiac surgery, postoperative troponin levels were lower and hemodynamic function better in patients receiving sevoflurane. A study comparing desflurane with propofol in patients undergoing off-pump coronary artery bypass showed similar results. In contrast, administration of a large-dose of propofol (120 μg/kg/min) or small-dose of propofol (60 μg/kg/min) during cardiopulmonary bypass, or titrating isoflurane throughout surgery, showed improved troponin levels and better hemodynamic function in the large-dose propofol group compared to the isoflurane or small-dose propofol group. This study suggests that cardio protection with propofol is dose-dependent.[102] Lastly, combinations of propofol with inhaled anesthetics may offer an optimal pre- and postconditioning strategy in patients scheduled for coronary bypass surgery. Isoflurane preconditioning combined with propofol postconditioning acts synergistically in attenuating postischemic myocardial reperfusion injury as determined by surrogate markers of myocardial injury and function.[103] Heart rate changes are variable when anesthesia is maintained with propofol. The extent of hypotension, the ability for the patient to compensate, and the use of any other concomitant drugs are likely the most important factors in determining what happens to the heart rate after propofol administration.

OTHER EFFECTS

Propofol, similar to thiopental, does not enhance neuromuscular blockade produced by neuromuscular blocking drugs. Propofol produces no effect on the evoked electromyogram or twitch tension; however, good or acceptable tracheal intubating conditions after propofol alone have been reported. Propofol does not trigger malignant hyperthermia and is an appropriate choice in patients with this condition.[104-106] Propofol after a single dose or a prolonged infusion does not affect corticosteroid synthesis or alter the normal response to adrenocorticotropic hormone (ACTH) stimulation. Propofol in the emulsion formulation does not alter hepatic, hematologic, or fibrinolytic function. Lipid emulsion per se reduces in vitro platelet aggregation, however. Anaphylactoid reactions to the present formulation of propofol have been reported. In at least some patients, the immune response was entirely due to propofol and not to the lipid emulsion. Most patients developing the anaphylactoid response to propofol had a previous history of allergic responses. Perhaps propofol should not be used in patients with multiple drug allergies.[107-109] Propofol alone in intralipid does not trigger histamine release. Fospropofol is metabolized to propofol and formate. Formate concentrations do not increase after fospropofol administration. Propofol also possesses significant antiemetic activity with small (subhypnotic) doses (i.e., 10 mg in adults). The median concentration of propofol with an antiemetic effect was 343 ng/mL, which also causes a mild sedative effect.[110] This concentration can be achieved by an initial dose of propofol infusion of 10 to 20 mg followed by 10 μg/kg/min. Propofol used as a maintenance anesthetic during breast surgery was more effective than 4 mg of ondansetron given as prophylaxis in preventing postoperative nausea and vomiting (PONV) (also see Chapter 80). Propofol as an infusion of 1 mg/kg/h (17 μg/kg/min) also has provided excellent antiemetic action after anticancer chemotherapy. At subhypnotic doses, propofol relieves cholestatic pruritus and is likely as effective as naloxone in treating pruritus induced by spinal opiates.

Propofol decreases polymorphonuclear leukocyte chemotaxis, but not adherence phagocytosis and killing. This action contrasts with the effect of thiopental, which inhibits all these chemotactic responses. However, propofol inhibits phagocytosis and killing of *Staphylococcus aureus* and *Escherichia coli*. There have been life-threatening systemic infections associated with the use of propofol.[111] In hospitals where these infections occurred, opened vials and syringes of propofol had positive cultures. The intralipid that acts as the solvent for propofol is an excellent culture medium. Disodium edetate or metabisulfite has been added to the formulation of propofol in an attempt to retard such bacterial growth. Strict aseptic technique still must be observed. The administration of propofol is associated with the development of pancreatitis,[112] which may be related to hypertriglyceridemia. Patients who developed hypertriglyceridemia tended to be older, had a longer ICU stay, and received propofol for a longer duration. If propofol is being used for prolonged sedation or at higher infusion rates (especially in elderly patients), serum triglyceride concentrations should be routinely monitored.

BOX 23.1 **Uses and Doses of Intravenous Propofol**

Induction of general anesthesia	1-2.5 mg/kg IV, dose reduced with increasing age
Maintenance of general anesthesia	50-150 μg/kg/min IV combined with N_2O or an opiate
Sedation	25-75 μg/kg/min IV
Antiemetic action	10-20 mg IV, can repeat every 5-10 min or start infusion of 10 μg/kg/min

IV, Intravenously; *N_2O,* nitrous oxide.

Uses

INDUCTION AND MAINTENANCE OF ANESTHESIA

Propofol is suitable for the induction and maintenance of anesthesia (Box 23.1). The intravenous induction dose is 1 to 2.5 mg/kg. Physiologic characteristics that best determine the appropriate dose to induce anesthesia are age, lean body mass, and central blood volume.[113] Propofol may be titrated on the basis of the BIS value for maintenance of anesthesia and to assure adequacy of anesthesia and prevention of overdosing. Premedication with an opiate or a benzodiazepine, or both, markedly reduces the necessary induction dose.[114-116] The induction dose needs to be reduced in elderly patients and a dose of 1 mg/kg (with premedication) to 1.75 mg/kg (without premedication) is recommended for inducing anesthesia in patients older than 60. Furthermore, older and sicker (ASA class III to IV) patients develop more profound hypotension, especially when propofol islcombined with an opiate (also see Chapter 65). To prevent hypotension in sicker patients or in patients presenting for cardiac surgery, intravenously administered fluids should be given as tolerated, and propofol titrated to achieve the desired anesthetic state. In general, for both pharmacokinetic and pharmacodynamic reasons elderly patients (>80 years old) require half the dose of young patients (<20 years)[117]. For induction in children, the ED_{95} (2-3 mg/kg) is increased, primarily because of pharmacokinetic differences. Children demonstrate a smaller central compartment, an increased metabolic clearance, and larger volumes of distribution of propofol relative to adult patients.[69] Propofol, when used for induction of anesthesia in short-lasting procedures, results in a significantly quicker recovery and an earlier return of psychomotor function compared with thiopental or methohexital, regardless of the anesthetic used for maintenance of anesthesia.

Several infusion schemes have been used to achieve adequate plasma concentrations of propofol. After an induction dose, an infusion of 100 to 200 μg/kg/min is usually needed. The infusion rate is titrated to individual requirements and the surgical stimulus. When combined with propofol, the required infusion rate and concentration of opiates, midazolam, clonidine, or ketamine should be reduced.[20,118] Because opioids alter the concentration of propofol required for adequate anesthesia, the time to awakening and recovery can be influenced by these drug combinations. Also, opioids affect both the pharmacokinetics and the pharmacodynamics of propofol. Alfentanil decreases the elimination clearance of propofol from 2.1 L/min to 1.9 L/min, the distribution clearance from 2.7 L/min to 2.0 L/min, and the peripheral volume of distribution from 179 L to 141 L. The pharmacokinetic parameters of propofol are affected by cardiac output, heart rate, and plasma alfentanil concentration.[39] Similarly, midazolam reduces propofol's metabolic clearance from 1.94 to 1.61 L/min, Cl_2 from 2.86 to 1.52 L/min, and Cl_3 from 0.95 to 0.73 L/min. Consequently, in the presence of both midazolam and alfentanil propofol concentrations become elevated by 20% to 30%.[53] The infusion rate required to achieve the combination with the shortest recovery is propofol, 1 to 1.5 mg/kg followed by 140 μg/kg/min for 10 minutes followed by 100 μg/kg/min, and alfentanil, 30 μg/kg followed by an infusion of 0.25 μg/kg/min, or fentanyl, 3 μg/kg followed by 0.02 μg/kg/min.

As indicated previously, increasing age is associated with a decrease in propofol infusion requirements, whereas these requirements are larger in children and infants. The blood levels of propofol alone for loss of consciousness are 2.5 to 4.5 μg/mL, and the blood concentrations (when combined with nitrous oxide) required for surgery are 2.5 to 8 μg/mL. Similar concentrations are necessary when propofol is combined with an opioid for a total IV technique. The knowledge of these levels and of the pharmacokinetics of propofol has enabled the use of pharmacokinetic model–driven infusion systems to deliver propofol as a continuous infusion for the maintenance of anesthesia. A meta-analysis of recovery data after either propofol for maintenance or the newer volatile anesthetics indicated only minor differences in times to reach recovery goals; however, the incidence of nausea and vomiting remained significantly less frequent in the patients given propofol for maintenance of anesthesia.

Propofol can be used as a maintenance of anesthesia infusion regimen for cardiac surgery. Using reduced and titrated doses of propofol for induction of anesthesia and titrated infusion rates of 50 to 200 μg/kg/min combined with an opioid for maintenance, propofol provides intraoperative hemodynamic control and ischemic episodes similar to those with either enflurane/opioid or a primary opioid technique.

Blood propofol concentrations increase in the presence of hemorrhagic shock. Shock affects the pharmacokinetics and pharmacodynamics of propofol. Shock results in slower intercompartmental clearances and shock shifts the concentration effect relationship to the left, demonstrating a 2.7-fold decrease in the effect-site concentration required to achieve 50% of the maximal effect in the BIS.[119] These pharmacokinetic changes may be reversed with intravenous fluid resuscitation. The propofol doses needed to reach a 50% decrease from baseline BIS, and no movement after noxious stimuli, are reduced by hemorrhagic shock by 54% and 38%, respectively. Hemorrhagic shock decreases the effect-site concentration that produced 50% of the maximal BIS effect from 11.6 ± 3.8 to 9.1 ± 1.7 μg/mL and that producing a 50% probability of movement from 26.8 ± 1.0 to 20.6 ± 1.0 μg/mL.[120]

SEDATION

Propofol has been evaluated for sedation during surgical procedures and for patients receiving mechanical ventilation in the ICU.[120a] As noted earlier, tolerance can occur with propofol. Increased propofol requirement occurs with repeated anesthetic administration in a limited time period in individual patients and an increased infusion requirement when propofol is infused for prolonged periods.[74] Infusion rates required for sedation to supplement regional anesthesia in healthy patients are half or less than the rates required for general anesthesia (i.e., 30-60 μg/kg/min). In elderly patients (>65 years old) and in sicker patients, the infusion rates that are necessary are markedly reduced up to 50% compared to 20-year-old patients. The infusion should be individually titrated to the desired effect. The pharmacokinetic profile of propofol makes it a suitable choice for long-term (days) sedation. This should always be weighed, though, against the hemodynamic side effects, tolerance, and rare occurrences of hypertriglyceridemia (and potential pancreatitis) or propofol infusion syndrome. Maintaining the smallest possible dose required for the desired level of sedation with potential "sedation holidays" should be considered as part of a long-term propofol sedation regimen. In addition, the FDA has specifically recommended against the use of propofol for the prolonged sedation of pediatric patients. The sedation guidelines of the American College of Critical Care Medicine also recommend "that patients receiving propofol for long-term sedation should be monitored for unexplained metabolic acidosis or arrhythmias. Drugs other than propofol should be considered for patients with escalating vasopressor or inotrope requirements or cardiac failure during large-dose propofol infusions." The recommended maximal dose of propofol infusion rate is 80 μg/kg/min (<5 mg/kg/h).[121] Generally, at propofol infusion rates more rapid than 30 μg/kg/min, patients are amnesic.

SIDE EFFECTS AND CONTRAINDICATIONS

In December 2016 the FDA issued a warning raising concerns about the potential risks to fetal brain development with general anesthetics, including propofol. Animal studies show that prolonged or repetitive propofol exposure to the developing fetal brain may be related to propofol neurotoxicity. Minimizing fetal exposure to propofol and other general anesthetics is therefore important and advisable.[121a,121b]

Next to its hypnotic effects, accumulating evidence suggests that propofol may affect cancer development through direct and indirect manners. Propofol exerts antitumor potential partly due to regulation of the expression and transfer of miRNAs. In addition, propofol impacts the degree of immunosuppression by modulating immune cells and cytokines. This results in reduced cancer cell mobility in some cancers and increased apoptosis of cancer cells in others. The clinical impact of the cancer-modulating effects of propofol needs further investigation.[121c] Induction of anesthesia with propofol is often associated with pain on injection, myoclonus, apnea, hypotension, and, rarely, thrombophlebitis of the vein into which propofol is injected.[122] Pain on injection is reduced by using a large vein, avoiding veins in the dorsum of the hand, and adding lidocaine to the propofol solution or changing the propofol formulation. Multiple other drugs and distraction techniques have been investigated to reduce the pain on injection of propofol. Pretreatment with a small dose of propofol, opiates, nonsteroidal anti-inflammatory drugs, ketamine, esmolol/metoprolol, magnesium, a flash of light, clonidine/ephedrine combination, dexamethasone, and metoclopramide all have been tested with variable efficacy.

Propofol infusion syndrome is a rare but lethal syndrome associated with infusion of propofol at 4 mg/kg/h or more for 48 hours or longer.[123] Yet, cases have been reported with smaller dosage schemes given for only 3 hours.[124] It was first described in children, but subsequently has been observed in critically ill adults.[125,126] The clinical features of propofol infusion syndrome are acute refractory bradycardia leading to asystole, in the presence of one or more of the following: metabolic acidosis (base deficit >10 mmol/L^{-1}), rhabdomyolysis, hyperlipidemia, and enlarged or fatty liver. Other features include cardiomyopathy with acute cardiac failure, skeletal myopathy, hyperkalemia, hepatomegaly, and lipemia. The symptoms and signs are the result of muscle injury and of the release of intracellular toxic contents. The major risk factors for its development are poor oxygen delivery, sepsis, serious cerebral injury, and large propofol dosage. Predisposing factors for the propofol infusion syndrome are likely genetic disorders impairing fatty acid metabolism, such as medium-chain acyl CoA (MCAD) deficiency and low carbohydrate supply. Because lipemia has been noted, a failure of hepatic lipid regulation, possibly related to poor oxygenation or a lack of glucose, may be the cause. In some cases, an increasing lipemia was the first indication of impending propofol infusion syndrome onset, so lipemia is a sign.

Barbiturates

HISTORY

Barbiturates were discovered in the early twentieth century. The first barbiturate to cause loss of consciousness within one arm-brain circulation time was hexobarbital. After the clinical introduction of thiopental by Waters and Lundy in 1934, thiopental became preferred clinically because of its rapid onset of action and short duration, without the excitatory effects of hexobarbital.[127] Although criticized after many casualties during the attack on Pearl Harbor as “the cause of more fatal casualties among the servicemen at Pearl Harbor than were the enemy bombs,” the barbiturates continued to be widely used in clinical practice.[128] Many other barbiturate derivatives have been synthesized throughout the past decades, yet none have enjoyed the clinical success and popularity of thiopental.

Physicochemical Characteristics

CHEMISTRY AND FORMULATION

Barbiturates are hypnotically active drugs that are derivatives of barbituric acid (2,4,6-trioxohexahydropyrimidine), a hypnotically inactive pyrimidine nucleus that is formed by the condensation of malonic acid and urea (Fig. 23.5). The two major classes of barbiturates are the oxybarbiturates and thiobarbiturates with either an oxygen at position 2 or with a sulfur in position 2, respectively. Through keto-enol tautomerization, the oxygen or sulfur in position 2 becomes a reactive species in the enol form. This allows for the formation of water-soluble barbiturate salts in alkaline solutions and permits the IV use of barbiturates. Although tautomerization to the enol form allows for the creation of salts, the substitution of the hydrogen attached to the carbon atom in position 5 with aryl or alkyl groups gives the barbiturates their hypnotic activity. Only thiopental and thiamylal, thiobarbiturates, and methohexital, an oxybarbiturate, have been used for induction of anesthesia (Fig. 23.6). The formulation of barbiturates involves preparation as sodium

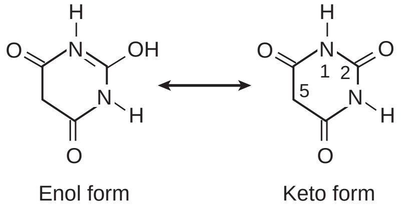

Fig. 23.5 The keto and enol tautomeric forms of barbituric acid with the sites of substitution in the hypnotically active barbiturates identified as 1, 2, and 5.

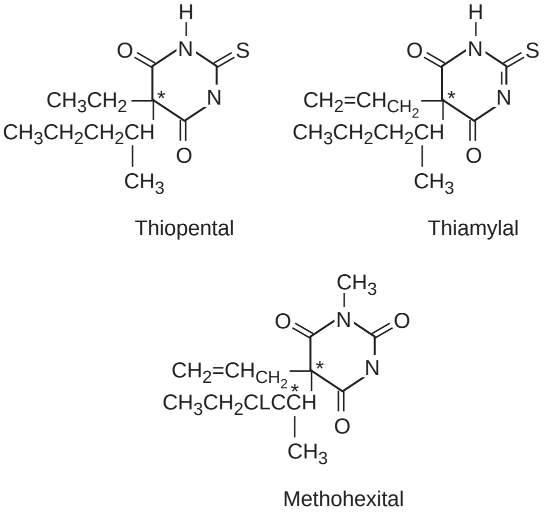

Fig. 23.6 Hypnotically active barbiturates commonly used for induction, with their asymmetric centers indicated by an asterisk.

salts (mixed with 6% by weight anhydrous sodium carbonate) and then reconstitution with either water, glucose 5%, or normal saline to produce a 2.5% solution of thiopental, a 2% solution of thiamylal, or a 1% solution of methohexital. The thiobarbiturates are stable for 1 week if refrigerated after reconstitution, and methohexital remains available for use for 6 weeks after reconstitution. Barbiturates cannot be reconstituted with lactated Ringer solution or mixed with other acidic solutions, as a decrease in the alkalinity of the solution can result in precipitation of the barbiturates as free acids. Examples of drugs that are not to be coadministered or mixed in solution with the barbiturates are atracurium, vecuronium, rocuronium, suxamethonium, alfentanil, sufentanil, dobutamine, dopamine, esketamine, and midazolam. Mixing of thiopental with vecuronium or pancuronium results in the formation of precipitate that may occlude the IV line during a rapid sequence induction of anesthesia.[129]

Structure-Activity Relationships

As noted earlier, substitutions at the 5, 2, and 1 positions confer different pharmacologic activities to the barbiturate nucleus. Substitutions at position 5 with either aryl or alkyl groups produce hypnotic and sedative effects, whereas substitution at C5 with a phenyl group produces anticonvulsant activity. An increase in length of one or both side chains of an alkyl group at C5 increases hypnotic potency. Barbiturates used in clinical practice have either an oxygen or sulfur at C2. Substitution of a sulfur at position 2 produces a more rapid onset of action, as with thiopental. The addition of a methyl or ethyl group at position 1 also may produce a more rapid onset of action, as with methohexital. However, excitatory side effects, including tremor, hypertonus, and involuntary movement, may occur upon administration.

Pharmacokinetics

METABOLISM

The barbiturates (with the exception of phenobarbital) are metabolized hepatically. The metabolites are almost all inactive, water-soluble, and excreted in the urine. Barbiturates are biotransformed by four processes: (1) oxidation of the aryl, alkyl, or phenyl moiety at C5; (2) *N*-dealkylation; (3) desulfuration of the thiobarbiturates at C2; and (4) destruction of the barbituric acid ring.[130] Oxidation is the most important pathway, producing polar (charged) alcohols, ketones, phenols, or carboxylic acids. These metabolites are readily excreted in the urine or as glucuronic acid conjugates in the bile. Hydrolytic cleavage of the barbituratic acid ring forms a minimal contribution to the total metabolism of barbiturates, since the ring is stable in vivo. Drugs that induce oxidative microsomes or long-term administration enhance the metabolism of barbiturates. The hepatic enzyme induction by barbiturates is the reason that they are not recommended for administration to patients with acute intermittent porphyria. Barbiturates may precipitate an attack by stimulating γ-aminolevulinic acid synthetase, the enzyme responsible for the production of porphyrins.[131]

As mentioned earlier, hepatic metabolism accounts for the elimination of all of the barbiturates with the exception of phenobarbital. Renal excretion accounts for 60% to 90% of phenobarbital excretion in an unchanged form. The alkalinization of urine with bicarbonate enhances the renal excretion of phenobarbital. Other barbiturates are excreted unchanged by the kidney only in trivial amounts.

Methohexital is metabolized in the liver by oxidation to an alcohol and *N*-dealkylation. Methohexital exhibits similar distribution half-lives, volumes of distribution, and protein bindings as thiopental. A marked difference exists, however, in plasma disappearance and elimination half-lives (4 hours for methohexital and 12 hours for thiopental). This difference is due to the threefold more rapid rate of hepatic clearance of methohexital (mean 7.8-12.5 mL/kg/min).[132] The hepatic extraction ratio of methohexital (clearance to hepatic blood flow) is approximately 0.5, indicating that the liver extracts 50% of the drug presented to it. This ratio differs from the smaller hepatic extraction ratio of thiopental (0.15).

Barbiturate pharmacokinetics have been described in physiologic and compartmental models.[133] Both of these pharmacokinetic models describe rapid redistribution as the primary mechanism that terminates the action of a single induction dose. Physiologic models of barbiturates describe a rapid mixing of the drug within the central blood volume followed by a quick distribution of the drug to highly perfused, low-volume tissues (i.e., brain) with a slower redistribution of the drug to lean tissue (muscle), which terminates the effect of the initial (induction of anesthesia) dose. In these models, adipose tissue uptake and metabolic clearance (elimination) play only a minor role in the termination of the effects of the induction dose. This is a result of the minimal perfusion ratio of adipose tissue compared with other tissues and the slow rate of removal. Compartmental model values for thiopental and methohexital, the most commonly used barbiturates for induction of anesthesia, are given in Table 23.1. The compartmental model explains the delay of recovery when a continuous infusion of a barbiturate is used. This model describes how the termination of effect becomes increasingly dependent on the slower process of uptake into and redistribution from adipose tissue and elimination clearance through hepatic metabolism. After prolonged infusions, the pharmacokinetics of barbiturate metabolism is best approximated by nonlinear Michaelis-Menten metabolism. In usual doses (4-5 mg/kg), thiopental exhibits first-order kinetics (i.e., a constant *fraction* of drug is cleared from the body per unit time); however, at very high doses of thiopental (300-600 mg/kg) with receptor saturation, zero-order kinetics occur (i.e., a constant *amount* of drug is cleared per unit time). The volume of distribution is slightly larger in female patients, causing a longer elimination half-life.[134] Pregnancy also increases the volume of distribution of thiopental, prolonging the elimination half-life.[135] Even at advanced stages of liver cirrhosis, the clearance of thiopental is not altered. Because of its lipophilicity, relatively large volume of distribution, and low rate of hepatic clearance, thiopental can accumulate in tissues, especially if given in large doses over a prolonged period. The plasma drug level increases when repeated doses of drug are given. Although not used in routine clinical practice, appropriately designed infusion schemes ensure constant blood levels, maintaining the desired hypnotic effect.

Pharmacology

MECHANISM OF ACTION

The mechanisms of action of barbiturates on the CNS are largely unknown, with the exception of their action on the $GABA_A$ receptor.[136,137] Perhaps the NMDA receptors are involved with the effects of barbiturates.[138-140] The effects of barbiturates on the CNS have been grouped into two categories: (1) enhancement of the synaptic actions of *inhibitory* neurotransmitters, and (2) blockade of the synaptic actions of *excitatory* neurotransmitters.[141] GABA is the principal inhibitory neurotransmitter in the mammalian CNS, and the $GABA_A$ receptor is the only site proven to be involved in barbiturate-induced anesthesia.[137] The $GABA_A$ receptor is a chloride ion channel, composed of five subunits, with specific sites of action for GABA, barbiturates, benzodiazepines, and other molecules. The binding sites are at the interface of the specific subunits, where the combination of the adjacent subunits determine the affinity and selectivity for drugs like propofol, etomidate, or pentobarbital. Of each subunit multiple types exist, leading to various compositions of the $GABA_A$ receptor. Progressive insights in the composition of these binding sites may be useful in developing novel clinical anesthetics.[141a] Barbiturate binding to the $GABA_A$ receptor enhances and mimics the action of GABA by increasing chloride conductance through the ion channel. This causes hyperpolarization of the cell membrane and increases the threshold of excitability of the postsynaptic neuron. At low concentrations barbiturates enhance the effects of GABA, decreasing the rate of dissociation of GABA from its receptor and increasing the duration of GABA-activated chloride ion channel openings. This enhancement of the action of GABA is likely responsible for the sedative-hypnotic effects of the barbiturates. At larger concentrations, the barbiturates activate the chloride channels directly, without the binding of GABA, acting as the agonist itself. The GABA-mimetic effect at slightly higher concentrations may be responsible for what is termed barbiturate anesthesia.[137]

The second mechanism of action of barbiturates involves the inhibition of the synaptic transmission of excitatory neurotransmitters, such as glutamate and acetylcholine. The actions of the barbiturates to block excitatory CNS transmission are specific for synaptic ion channels. Thiopental, however, may exert GABA-independent effects on the glutaminergic-NMDA system. In two studies on effects in the rat prefrontal cortex, thiopental decreased extracellular glutamate levels in the CNS and decreased NMDA-gated currents in a concentration-dependent manner.[139,140]

Effects on Cerebral Metabolism (Also see Chapter 57)

Barbiturates, like other CNS depressants, have potent effects on cerebral metabolism. A dose-related depression of cerebral metabolic oxygen consumption rate ($CMRO_2$) progressively slows the EEG, reduces the rate of adenosine triphosphate consumption, and enhances protection from partial cerebral ischemia. The relationship between depressed metabolism and drug requirement was shown when thiopental was not eliminated (i.e., sustained with an extracorporeal circulation pump).[142] When the EEG became isoelectric, a point at which cerebral metabolic activity is roughly 50% of baseline,[143] no further decreases in $CMRO_2$ occurred. These findings support the hypothesis that metabolism and function of the brain are coupled. Barbiturates reduce the metabolic activity concerned with neuronal signaling and impulse traffic, not the metabolic activity corresponding to basal metabolic function. The only way to suppress baseline metabolic activity concerned with cellular activity is via hypothermia.[143] The effect of barbiturates on cerebral metabolism is maximized at a 50% depression of cerebral function, leaving all metabolic energy for the maintenance of cellular integrity. With the reduction in $CMRO_2$, there is a parallel reduction in cerebral perfusion, which is seen in decreased cerebral blood flow (CBF) and ICP. With reduced $CMRO_2$, cerebral vascular resistance increases, and CBF decreases.[144] The ratio of CBF to $CMRO_2$ remains unchanged. Even though the mean arterial pressure (MAP) decreases, barbiturates do not compromise the overall CPP because the CPP equals MAP minus ICP. In this relationship, ICP decreases more than MAP after barbiturate administration, preserving CPP.

Pharmacodynamics

Sufficient doses of barbiturates cause loss of consciousness, amnesia, and respiratory and cardiovascular depression, known as general anesthesia. The response to pain and other noxious stimulation during general anesthesia seems to be depressed. Pain studies reveal that barbiturates may decrease the pain threshold. This antianalgesic effect occurs only with low blood levels of barbiturates, which might be achieved with small doses of thiopental for induction of anesthesia or after emergence from thiopental. The amnesic effect of barbiturates is less pronounced than that produced by benzodiazepines.

Effects on the Central Nervous System

Drugs with high lipid solubility and a low degree of ionization cross the blood-brain barrier rapidly, producing a fast onset of action.[137] Most barbiturates exist in a nonionized form. Thiopental and methohexital are more lipid soluble than pentobarbital, which is clinically reflected by the more rapid onset of action of thiopental and methohexital compared to pentobarbital.[145] Only the nonionized form of a drug can directly traverse the cellular membranes. Thiopental has a pK_a of 7.6. Approximately 50% of thiopental is nonionized at physiologic pH, which accounts partly for the rapid accumulation of thiopental in the cerebrospinal fluid (CSF) after IV administration.[146] Methohexital is 75% nonionized at pH 7.4, which may explain the slightly more rapid effect of methohexital compared to thiopental. As pH decreases, with poor perfusion, barbiturates have a larger fraction of nonionized drug available to cross the blood-brain barrier.[146]

The onset of action in the CNS is affected by protein binding, because only unbound drug (free drug) can cross the blood-brain barrier.[147] Barbiturates are highly bound to albumin and other plasma proteins, where the thiobarbiturates are more highly protein bound than are the oxybarbiturates. The degree of protein binding of a drug is influenced by the physiologic pH and disease states, which alter the absolute amount of protein. Most barbiturates tend to experience peak protein binding at or around pH 7.5. The final factor governing the rapidity of drug penetration of the blood-brain barrier is the plasma drug concentration, causing a concentration gradient. The two primary determinants of the plasma concentration are the *dose* administered and the *rate* (speed) of administration. As the dose of thiopental over the same time is increased, an increased percentage of patients will be anesthetized.[148] Concerning absolute dose, 2 mg/kg produced anesthesia in 20% of patients, whereas a dose of 2.4 mg/kg produced anesthesia in 80% of patients. Similarly, the speed of injection influences the effect of thiopental. A smaller amount of drug is required to produce anesthesia when the dose rate of the administration is over 5 seconds as opposed to over 15 seconds.

Because of the equilibrium between brain concentration and plasma concentration, factors that determine the rate of onset of barbiturate effects also affect their termination. Lipid solubility, degree of ionization, and CSF drug concentration affect the movement of drug from the CSF to plasma. As plasma levels decrease, drug levels in the brain and CSF decrease. The most important factors in the termination of drug effect are those that govern plasma disappearance of the drug. These are generally divided into a rapid redistribution phase and a slow metabolic and second redistribution phase. In a classic pharmacologic study, Brodie and coworkers[149] showed that awakening from thiopental occurred because the plasma concentration rapidly declined. They further showed that the cause of the rapid plasma decay of thiopental was not metabolism of the drug but was rather due to a redistribution of the drug to other tissues throughout the body. The relationship of the plasma drug level and drug redistribution to the onset and termination of effect is illustrated in Fig. 23.7. Clinically, patients awake from a single dose of thiopental 5 to 10 minutes after administration, as the drug is redistributed from highly perfused CNS tissues to well-perfused lean tissues. The termination of effect after multiple drug administrations or constant infusion depends on the elimination of the drug from the blood, which becomes increasingly more dependent on first-order metabolism than redistribution and is a function of its context-sensitive decrement time (see Fig. 23.3). Awakening may be delayed in older patients because of increased CNS sensitivity, alterations in metabolism, or decreased central volume of distribution relative to younger adults.[150] The initial volume of distribution is less in elderly patients than in young patients, which explains a smaller dose requirement for the onset effect. Pediatric patients (<13 years old) seem to have a more rapid rate of total clearance and a shorter rate of plasma thiopental clearance than do adults, which theoretically might result in earlier awakening, especially after multiple doses of the drug.[151] There is little difference in distribution of thiopental and methohexital, which may explain the similar wakeup times. There is, however, a difference in the rate of total body clearance, being more rapid for methohexital. This disparity explains the difference found in the psychomotor skills of patients and the earlier full recovery after methohexital. Despite some residual effects, methohexital is cleared more rapidly than thiopental, which explains why methohexital is preferred for use by some clinicians when rapid awakening is desirable, such as in outpatient anesthesia. Prolongation of early and late recovery by the barbiturates is the primary reason behind the fact that they have been largely replaced by propofol.

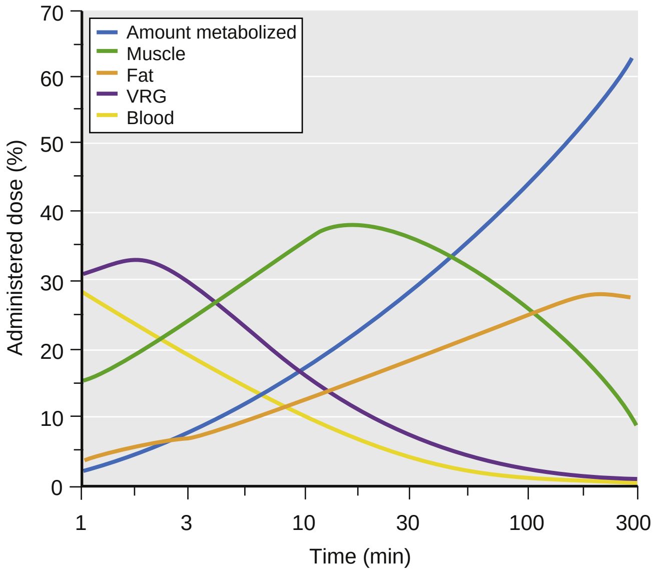

Fig. 23.7 After delivery of an IV bolus, the percentage of thiopental remaining in blood rapidly decreases as drug moves from blood to body tissues. The time to attainment of peak tissue levels is a direct function of tissue capacity for barbiturate relative to blood flow. A larger capacity or smaller blood flow is related to a longer time to a peak tissue level. Initially, most thiopental is taken up by the vessel-rich group *(VRG)* of tissues because of their high blood flow. Subsequently, drug is redistributed to muscle and to a lesser extent to fat. Throughout this period, small but substantial amounts of thiopental are removed and metabolized by the liver. In contrast to removal by tissues, this removal is cumulative. The rate of metabolism equals the early rate of removal by fat. The sum of this early removal by fat and metabolism is the same as the removal by muscle. (Redrawn from Saidman LJ. Uptake, distribution and elimination of barbiturates. In: Eger EI [ed]. *Anesthetic Uptake and Action*. Baltimore: Williams & Wilkins; 1974.)

Effects on the Respiratory System

Barbiturates produce dose-related central respiratory depression. The evidence for central depression is a correlation between EEG suppression and diminished minute ventilation. Peak respiratory depression (as measured by the slope of carbon dioxide concentration in the blood) and maximum depression of minute ventilation after delivery of thiopental (3.5 mg/kg) occurs 1 to 1.5 minutes after administration. These variables return to predrug levels rapidly, and within 15 minutes the drug effects are barely detectable.[152] Patients with chronic lung disease are slightly more susceptible to the respiratory depression of thiopental. The ventilatory pattern with thiopental induction has been described as "double apnea," that is an initial apnea of a few seconds occurring upon drug administration, succeeded by a few breaths of reasonably adequate tidal volume, which is followed by a more prolonged period of apnea, typically of approximately 25 seconds. This apnea occurs in at least 20% of cases. During the induction of anesthesia with thiopental, ventilation must be assisted or controlled to provide adequate respiratory exchange. Like thiopental, methohexital is a central respiratory system depressant.[152] Induction doses (1.5 mg/kg) significantly decrease the slope of the ventilatory response to carbon dioxide, with a maximal reduction at 30 seconds after drug administration.[153] The peak decrease in tidal volume occurs 60 seconds after methohexital administration. All variables return to baseline within 15 minutes. In contrast to the effects on ventilation, patients awaken within about 5 minutes after the administration of methohexital (1.5 mg/kg).

Effects on the Cardiovascular System

Cardiovascular depression from barbiturates is a result of central and peripheral (direct vascular and cardiac) effects. The primary cardiovascular effect of a barbiturate during induction of anesthesia is peripheral vasodilation causing a pooling of blood in the venous system. Mechanisms for the decrease in cardiac output include (1) direct negative inotropic action, due to a decrease of calcium influx into the cells, (2) decreased ventricular filling, due to increased capacitance, and (3) transiently decreased sympathetic outflow from the CNS.[154] The increase in heart rate (10% to 36%) that accompanies thiopental administration probably results from the baroreceptor-mediated sympathetic reflex stimulation of the heart in response to the decrease in output and pressure. The cardiac index, as well as the MAP, is unchanged or reduced. Hemodynamic changes are dependent on the infusion rate of thiopental. In the dose ranges hitherto studied, no relationship between plasma thiopental level and hemodynamic effect has been found. There is little difference in the responses after thiopental and methohexital administration in patients with heart disease. The increase in heart rate (11%-36%) encountered in patients with coronary artery disease anesthetized with thiopental (1-4 mg/kg) is potentially deleterious because of the obligatory increase in myocardial oxygen consumption that accompanies the increased heart rate. In a study in dogs, thiopental prolonged the QT interval, flattened T waves, and increased QT dispersion during and after induction.[150] Thiopental may not be the most appropriate choice for patients with a susceptibility to ventricular dysrhythmias or a prolonged QT interval, such as acidotic patients or conditions that prolong the QT interval, such as long-term dialysis or advanced cirrhosis. Patients who have normal coronary arteries have no difficulty in maintaining adequate coronary blood flow to meet the increased myocardial oxygen consumption.[155] Thiopental should be avoided in hypovolemic patients because there is a significant reduction in cardiac output (69%) and a significant decrease in arterial blood pressure.[156] Patients without adequate compensatory mechanisms may have serious hemodynamic depression with a thiopental induction of anesthesia.

Other Effects

The side effects of injecting barbiturates include a garlic or onion taste (40% of patients), allergic reactions, local tissue irritation, and rarely, tissue necrosis. A transient urticarial rash may develop on the head, neck, and trunk. More severe reactions such as facial edema, hives, bronchospasm, and anaphylaxis can occur. Treatment of anaphylaxis is symptomatic. Thiopental and thiamylal produce fewer excitatory symptoms with induction than methohexital, which produces cough, hiccups, tremors, and twitching approximately five times more often. Tissue irritation and local complications may occur more frequently with the use of thiopental and thiamylal than with methohexital.

The consequences of accidental arterial injection may be severe. The degree of injury is related to the concentration of the drug. Treatment consists of (1) dilution of the drug by the administration of saline into the artery, (2) heparinization to prevent thrombosis, and (3) brachial plexus block. Overall, the proper administration of thiopental intravenously is remarkably free of local toxicity.

Phenobarbital is used experimentally as an inducer of the cytochrome P450 (CYP) system in rodents, in particular of the CYP2B enzymes. In human hepatocyte culture, phenobarbital acts as an inducer of the CYP2B6, CYP2C9, CYP2C19, and CYP3A4 enzymes. This phenomenon may cause changes in the metabolism of drugs that are administered concomitantly.[157] On the other hand, the metabolism of thiopental can be influenced by concomitant drugs like selective serotonin reuptake inhibitors (SSRIs). These drugs are used frequently by patients who are treated by electroconvulsive therapy, in whom an induction with thiopental or thiamylal is performed.[158]

Uses

INDUCTION AND MAINTANANCE OF ANESTHESIA

Barbiturates are used clinically for induction and maintenance of anesthesia and premedication. Methohexital is the drug of choice for providing anesthesia during electroconvulsive therapy.[159] Other barbiturates used in this field are thiopental and thiamylal. Less frequently, barbiturates are used to provide cerebral protection in patients at risk of developing incomplete ischemia. The three barbiturates that are used most commonly for IV anesthesia induction and maintenance are thiopental, thiamylal, and methohexital. Thiopental is an excellent drug to use for induction of anesthesia. The prompt onset (15-30 seconds) of action and smooth induction are advantages for this drug. The rapid emergence, particularly after single use for induction, also was a reason for the widespread use of thiopental in this setting. Thiopental can be used to maintain general anesthesia because repeated doses reliably sustain unconsciousness and contribute to amnesia but should not be the drug of first choice as the hypnotic component in balanced anesthesia. A review of the role of anesthetics on the risk of awareness during surgery show that benzodiazepines reduce awareness compared to thiopental, ketamine, and placebo. Wakefulness is reduced by ketamine and etomidate, compared with thiopental. The evidence is not strong due to the risk of bias, the very small event rate, and the heterogeneity in definition of awareness.[160]

Methohexital is the only IV barbiturate used for induction of anesthesia that can compete with thiopental. With a dose of 1 to 2 mg/kg, induction and emergence from anesthesia is rapid. Methohexital also may be used as a hypnotic component to maintain anesthesia. Similar to thiopental, it is not an analgesic. Additional opioids or volatile anesthetics are required to provide a balanced technique satisfactory for general anesthesia during surgery. Because methohexital is

TABLE 23.4 Recommended Doses of Barbiturates for Anesthesia Induction and Maintenance

Drug	Induction Dose (mg/kg)*,†	Onset (s)	Intravenous Maintenance Infusion
Thiopental	3-4	10-30	50-100 mg every 10-12 min
Methohexital	1-1.5	10-30	20-40 mg every 4-7 min

*Adult and pediatric intravenous doses are roughly the same in milligrams per kilogram.

†Methohexital can be given rectally in pediatric patients as a 20 to 25 mg/kg/dose.

From Reves JG, Glass P, Lubarsky DA, et al. Intravenous anesthetics. In: Miller RD, Eriksson LI, Fleischer LA, et al, eds. *Miller's Anesthesia,* 7th ed. Philadelphia: Churchill Livingstone; 2010: 719–768.

cleared more rapidly than thiopental, it may be preferred to thiopental for the maintenance of anesthesia, as accumulation and saturation of peripheral sites takes longer. For brief infusion (<60 minutes), recovery from a methohexital infusion titrated to maintain hypnosis (50-150 µg/kg/min) is similar to that provided by propofol. There are probably upper limits of safe infusion doses yet to be defined, but seizures have occurred in neurosurgical patients after large doses of methohexital (24 mg/kg).[154] Methohexital may be given rectally and is absorbed rapidly, and can be used as a premedication drug in pediatric patients. The dose recommended for this use is 25 mg/kg rectal instillation (10% solution through a 14F catheter, 7 cm into rectum).[161] With this method of administration, sleep onset is rapid: mean peak plasma levels occur within 14 minutes.

Dosing

Dosing for the two most commonly used barbiturates is listed in Table 23.4. The usual doses of thiopental (3-4 mg/kg) and thiamylal (3-4 mg/kg) are about twice the dose of methohexital (1-2 mg/kg). In dose-response studies, the ED_{50} for thiopental ranged from 2.2 to 2.7 mg/kg, and the ED_{50} for methohexital was 1.1 mg/kg.[147] There is less interpatient variability in the dose response to barbiturates than to benzodiazepines when used for anesthesia induction, but there still is significant variability in the dose of thiopental required to induce anesthesia.[148] Interpatient dose variability is related to the presence of hemorrhagic shock, cardiac output, lean body mass, obesity, gender, and age. Hemorrhagic shock, lean body mass, age, and obesity explain variability of patient response owing to a decrease in the central volume of distribution. Finally, patients who have severe anemia, burns, malnutrition, widespread malignant disease, uremia, ulcerative colitis, or intestinal obstruction also require smaller induction doses of barbiturates.

Contraindications

The following conditions should be considered a contraindication for the use of IV barbiturates: (1) when there is respiratory obstruction or an inadequate airway, thiopental may worsen respiratory depression; (2) severe cardiovascular instability or shock contraindicate its use; (3) status asthmaticus is a condition in which airway control and ventilation may be worsened further by thiopental; (4) porphyria may be precipitated or acute attacks may be accentuated by the administration of thiopental; and (5) without proper induction equipment (IV instrumentation) and airway equipment (means of artificial ventilation), thiopental should not be administered.

Benzodiazepines

INTRODUCTION

The benzodiazepines have become a category of drugs widely used in anesthesia as anxiolytics, sedatives, and hypnotics. They exert their action through $GABA_A$ receptors, which are the key targets that mediate most of the clinically important effects of IV anesthetics.[162] In the clinical practice of daily anesthesia, midazolam is often used immediately before induction of anesthesia. The other agonists, diazepam, lorazepam, temazepam, and the antagonist flumazenil are sometimes used. Remimazolam, an ultrashort-acting $GABA_A$ receptor agonist, may be a useful new benzodiazepine in future anesthetic practice. Benzodiazepines are widely prescribed, and addiction to these drugs is a worldwide concern. Research is ongoing to elucidate the neural mechanism of the reward-related effects of benzodiazepines. Reynolds and associates conclude in their findings that α_2- and α_3-subunit–containing $GABA_A$ receptors are implicated as key mediators of the reward-related effects of benzodiazepines. This finding has important implications for the development of new drugs with less addictive properties.[163]

Surgical treatment of tumors is often the first line for several types of cancer. Several factors influence the metastatic spread of residual cancer cells. Midazolam is widely used during general anesthesia. Research in vitro and in vivo conclude that midazolam in contrast to dexmedetomidine has antitumorigenic properties in certain types of cancer in supraclinical dosage.[163a]

Benzodiazepines were discovered in 1954 by Sternbach and in 1959 chlordiazepoxide (Librium) was the first benzodiazepine patented. Diazepam was synthesized in 1963 in a search for a better compound and was used intravenously to induce anesthesia in 1965.[164] Oxazepam (Seresta), a metabolite of diazepam, was synthesized in 1961 by Bell. Lorazepam (Ativan), a 2′chloro-substitution product of oxazepam, was synthesized in 1971 in an attempt to produce a more potent benzodiazepine. The next major achievement was Fryer and Walser's synthesis in 1976 of midazolam (Versed, Dormicum), the first clinically used water-soluble benzodiazepine, produced primarily for use in anesthesia.[165] An ultrashort-acting benzodiazepine, remimazolam, is in its phase III trial and is promising.[166]

Physicochemical Characteristics

Four benzodiazepine receptor agonists are commonly used in anesthesia: midazolam, diazepam, lorazepam, and temazepam (Fig. 23.8). The physicochemical characteristics of the benzodiazepines used in anesthesia are listed in Table 23.5. These six molecules are relatively small and are lipid soluble at physiologic pH.

Of the clinically used benzodiazepines, midazolam is the most lipid soluble in vivo,[167] but because of its pH-dependent solubility, it is water soluble when formulated in a buffered acidic medium (pH 3.5). The imidazole ring of midazolam accounts for its stability in solution and its lipophilicity due

Enhancement of GABAergic activity: neuropharmacological effects of benzodiazepines and therapeutic use in anesthesiology. *Pharmacol Rev*. 2011;63(1):243–267.

to rapid closing of the imidazole ring at physiological pH. The high lipophilicity of the compounds accounts for the rapid CNS effect and relatively large volumes of distribution.

Pharmacokinetics

The four benzodiazepines used in anesthesia are classified as short-acting (midazolam), intermediate-acting (lorazepam, temazepam), and long-acting (diazepam), according to their metabolism and plasma clearance (Table 23.6). The plasma disappearance curves of all benzodiazepines can be best described by a two- or three-compartment model.

Protein binding and volumes of distribution are not much different among these four benzodiazepines, but the clearance is significantly different. Factors that may influence the pharmacokinetics of benzodiazepines are age, gender, race, enzyme induction, and hepatic and renal disease. In addition, the pharmacokinetics of the benzodiazepines are affected by obesity. The volume of distribution is increased as drug diffuses from the plasma into the adipose tissue. Although clearance is not altered, elimination half-lives are prolonged, owing to the increased volume of distribution and delayed return of the drug to the plasma in obese patients.[168] Generally, sensitivity to benzodiazepines in some patient groups, such as elderly patients, is greater despite relatively modest pharmacokinetic changes; factors other than pharmacokinetics must be considered when these drugs are used.

Midazolam: After oral ingestion midazolam is absorbed completely and the peak plasma concentration is achieved in 30 to 80 minutes.[169] The bioavailability is less than 50% due to a significant first-pass metabolism in the intestinal wall and the liver.[169,170] After IV administration, midazolam is rapidly distributed, with a distribution half-life of 6 to 15 minutes.[170] The plasma protein binding is high: 94% to 98%.

The hepatic extraction ratio is low, ranging from 0.30 to 0.44, but is higher than the unbound free fraction of midazolam in plasma.[169] Thus, the protein binding is not a restrictive factor in drug extraction by the liver. With this intermediate hepatic extraction ratio, the metabolic clearance of midazolam may be susceptible both to changes in enzyme activity and to changes in hepatic blood flow.

The elimination half-life ranges from 1.7 to 3.5 hours.[170,171] The plasma clearance ranges from 5.8 to 9.0 mL/kg/min and is higher compared to that of the other benzodiazepines. This is due to the fused imidazole ring, which is rapidly oxidized in vivo—much more rapidly than the methylene group of the diazepine ring of other benzodiazepines.[172]

The pharmacokinetics of midazolam are affected by obesity, age, hepatic cirrhosis, and severity of critical illness. Because of its high lipophilicity (at physiological pH), midazolam distributes preferably to adipose tissue resulting in

TABLE 23.6 Pharmacokinetic Parameters of the Benzodiazepines

	Elimination half-life (h)	Clearance (mL/kg/min)	Vd (L/kg)	Plasma Protein Binding (%)	Reference

a prolonged elimination half-life in obese patients.[168] Liver cirrhosis reduces plasma clearance of midazolam due to decreased metabolism.[173]

Midazolam is metabolized by CYP3A4 and CYP3A5[174] to 1-hydroxymethylmidazolam (= α-hydroxymidazolam) and 4-hydroxymidazolam.[175] These metabolites possess similar sedative activities compared to the parent compound and, when given over a longer time, these metabolites may accumulate. These metabolites are rapidly conjugated and excreted in the urine and have, like midazolam, a marked increase in peripheral volume of distribution in obese/overweight adolescents.[175a] In comparison, 1-hydroxymethylmidazolam is less potent than its parent compound, the affinity to the receptor is about 60%, and weaker than that of midazolam. The metabolites are cleared more rapidly than midazolam itself, making them of little concern in patients with normal hepatic and renal function. In patients with renal impairment, though, they can cause profound sedation.[176]

Diazepam: After oral ingestion the bioavailability is about 94%.[177] Time to peak plasma concentrations after oral ingestion is approximately 60 minutes.[178] Diazepam is extensively bound to plasma proteins; the volume of distribution ranges from 0.7 to 4.7 L/kg. The plasma clearance of diazepam ranges from 0.2 to 0.5 mL/kg/min.[179]

The pharmacokinetics of diazepam are affected by obesity and liver dysfunction and particularly by age. Increasing age reduces the clearance of diazepam significantly.[180]

Metabolism occurs in the liver and is mediated mainly by CYP2C19 and CYP3A4. This accounts for 80% of the biotransformation of diazepam.[181-183] The metabolite N-desmethyldiazepam has pharmacodynamic characteristics similar to those of diazepam, but has a much slower elimination half-life extending to 200 hours. N-desmethyldiazepam is further metabolized to oxazepam, which is also pharmacologically active.

Temazepam, another metabolite of diazepam, is mainly conjugated to temazepam glucuronide and a smaller part is demethylated to oxazepam and thereafter conjugated to oxazepam-glucuronide.[184]

Lorazepam: The oral bioavailability is high, nearly 90%. Peak plasma concentrations are reached approximately 2 hours after oral ingestion, the mean elimination half-life is 15 hours, with a range of 8 to 25 hours.[185] Lorazepam has a large volume of distribution from 0.8 to 1.3 L/kg,[186] and it is highly bound to plasma proteins (>90%).

The clearance of lorazepam is 0.8 to 1.8 mL/kg/min. Lorazepam is conjugated in the liver to an inactive glucuronide and up to 70% is excreted in urine. The pharmacokinetics of lorazepam is little altered by age, and not altered by gender or renal disease, but clearance is decreased by hepatic dysfunction.[187]

Remimazolam (CNS 7056)

Remimazolam, a new short-acting $GABA_A$ receptor agonist with high affinity to the GABA receptor, is rapidly degraded in plasma by nonspecific esterases to its carboxylic acid metabolite CNS 7054. The incorporation of a carboxylic ester moiety into the benzodiazepine core of remimazolam renders it susceptible to nonspecific tissue esterases.[188] Preclinical studies in sheep showed a more rapid onset of action, greater depth of sedation, and more rapid recovery than midazolam. In sheep, remimazolam showed no dose-dependent depth of sedation like propofol.[189] In humans, remimazolam is eliminated by first-order pharmacokinetics, with no clear relationship registered between body weight and elimination clearance. Accumulation after prolonged infusion is unlikely. The clearance of remimazolam was rapid (overall mean clearance 70.3 ± 13.9 L/hr) and the volume of distribution moderately large (steady-state volume of distribution is 34.8 ± 9.4 L). No clear relation exists between body weight and systemic clearance. Level and duration of sedation are dose-dependent in humans.[190] Remimazolam trials conclude a safe administration for procedural sedation; it allows a faster recovery of neuropsychiatric function compared to midazolam. Possible benefit compared to propofol is the safe administration by endoscopists instead of healthcare providers trained in anesthesia.

Pharmacodynamics

Benzodiazepines act selectively at the $GABA_A$ receptor, which mediates fast inhibitory synaptic transmission in the CNS. Benzodiazepines enhance the response to GABA by facilitating the opening of the GABA-activated chloride channels resulting in hyperpolarization. A series of compounds are candidates as endogenous ligand of the $GABA_A$ receptor, such as diazepam binding inhibitor and other substances. This is an area of ongoing research.[191]

Translocator protein (TSPO, 18 kDa), first described as a peripheral binding site for benzodiazepines, which are not associated with GABA receptors, are expressed throughout the body and brain. While their precise function and pharmacologic significance remain only partly known, the TSPO role has many proposed functions depending on the tissue, like cholesterol transport, regulatory role in the heart, and immunomodulation related to inflammatory activation.[192]

EFFECTS ON THE CENTRAL NERVOUS SYSTEM

All benzodiazepines have hypnotic, sedative, anxiolytic, amnesic, anticonvulsant, and centrally produced muscle-relaxing properties. They may differ to some extent in their potency and efficacy with regard to some of these pharmacodynamic actions (e.g., anticonvulsive action). The neurotransmitter GABA is an inhibitory neurotransmitter and controls the state of a chloride ion channel. Activation of this chloride ion channel results in neuronal hyperpolarization (increased membrane potential in the direction away from the threshold potential) and accounts for the classification of the GABA system as "inhibitory." Benzodiazepines bind to their receptors with high affinity; the binding is stereospecific and saturable; the order of receptor affinity (potency) of three agonists is lorazepam > midazolam > diazepam. Midazolam is approximately 3 to 6 times, and lorazepam 5 to 10 times, as potent as diazepam.[193] As indicated previously, the mechanism of action of benzodiazepines is reasonably well understood.[194,195] The interaction of benzodiazepine ligands with the $GABA_A$ receptor is one of the few examples in which the complex systems of biochemistry, molecular pharmacology, genetic mutations, and clinical behavioral patterns can to some extent be explained. $GABA_A$ subtypes mediate the different effects (amnesic, anticonvulsant, anxiolytic, and sleep).[195] The $GABA_A$ receptor is a pentameric assembly built from 18 or more subunits (Fig. 23.9). Many different combinations of this pentameric assembly occur in different parts of the brain; linking this diversity to physiological function and pharmacologic specificity may be possible. The α-subunit of the pentameric complex occurs in six isoforms (α_1-α_6).[187] Sedation, anterograde amnesia, and anticonvulsant properties are mediated via α_1-subunits of the $GABA_A$ receptors,[195] and anxiolysis and muscle relaxation are mediated via the α_2-subunits. The "benzodiazepine receptors" are found in highest densities in the olfactory bulb, cerebral cortex, cerebellum, hippocampus, substantia nigra, and inferior colliculus, where lower densities in the striatum, lower brainstem, and spinal cord are found. Spinal cord benzodiazepine receptors can play an important role in analgesia; however, further elucidation of the mechanism of action of this drug class is required.[196] Intrathecal midazolam reduces excitatory GABA-mediated neurotransmission in interneurons, leading to a decrease in the excitability of spinal dorsal horn neurons.[196] A meta-analysis shows that intrathecal midazolam improves perioperative analgesia and reduces nausea and vomiting.[197]

The benzodiazepines reduce the $CMRO_2$ in a dose-related manner. Midazolam and diazepam maintain a relatively normal ratio of CBF to $CMRO_2$. [198] Midazolam, diazepam, and lorazepam all increase the seizure initiation threshold to local anesthetics and decrease the mortality rate in mice exposed to lethal doses of local anesthetics. Midazolam has neuroprotective effects by preventing lipid peroxidation and mitochondrial damage. There are indications in rats that the peripheral benzodiazepine receptor is involved in these actions.[199]

Enhancement of GABAergic activity: neuropharmacological effects of benzodiazepines and therapeutic use in anesthesiology. *Pharmacol Rev*. 2011;63[1]:243–267.)

Effects on the Respiratory System

Benzodiazepines, similar to most IV anesthetics, produce dose-related central respiratory system depression. The benzodiazepines affect respiration in two different ways. First, they have an effect on the muscular tone leading to an increased risk of upper airway obstruction.[200] Second, they flatten the response of the respiratory curve to carbon dioxide.[201] In addition, sedative doses of midazolam depress the hypoxic ventilatory response in humans.[202]

Benzodiazepines and opioids produce additive or supra-additive (synergistic) respiratory depression, even though they act at different receptors.[203] Old age, debilitating disease, and other respiratory depressant drugs increase the incidence and degree of respiratory depression and apnea by benzodiazepines.

Effects on the Cardiovascular System

The hypothalamic paraventricular nucleus (PVN) is an important site for autonomic and endocrine homeostasis of the cardiovascular system. The PVN integrates afferent stimuli to regulate blood volume; the rostral ventrolateral medulla is the dominant brain region for tonic regulation of arterial blood pressure.[204] Under normal circumstances, the sympathetic nervous system is tonically inhibited. This inhibition is dependent on GABAergic signaling and nitric oxide.[205]

Benzodiazepines, when used alone, have modest hemodynamic effects. The predominant hemodynamic change is a modest decrease in arterial blood pressure, resulting from a decrease in systemic vascular resistance. The mechanism by which benzodiazepines maintain relatively stable hemodynamics involves the preservation of homeostatic reflex mechanisms. The hemodynamic effects of midazolam and diazepam are dose related, however, there is a plateau plasma drug effect above which little change in arterial blood pressure occurs. The plateau plasma level for midazolam is 100 ng/mL, and that for diazepam is about 900 ng/mL. Heart rate, ventricular filling pressures, and cardiac output are maintained after induction of anesthesia with benzodiazepines. More recent studies using heart rate variability variables as measurements to evaluate the effect of benzodiazepines on autonomic neurocardiac regulation conclude a biphasic effect. First, the vagal tone reduces and second, the cardiac pacemaker may decrease using intravenous premedication doses. In patients with increased left ventricular filling pressures, diazepam and midazolam produce a "nitroglycerin-like" effect by decreasing the filling pressure and increasing cardiac output. Notably, the stress of endotracheal intubation and surgery are not blocked by midazolam.

Drug Interactions

PHARMACOKINETIC DRUG INTERACTIONS

The pharmacokinetics of benzodiazepines may be altered by drug interactions. As cytochrome P450 is often involved in the metabolism of the benzodiazepines, drugs inducing or inhibiting CYP function often cause alterations in the pharmacokinetics of the benzodiazepines.

CYP-mediated drug interactions have extensively been examined utilizing midazolam, which is almost completely metabolized by CYP, particularly CYP3A4.

The inhibition of CYP3A by concomitantly administered drugs like—among many others—the azole antifungal agents, results in significant inhibition of the metabolism of midazolam.[206] Orally administered midazolam is especially affected by these inhibitors due to reduction of the first-pass metabolism elimination.[207]

Diazepam is primarily metabolized by CYP2C19 and CYP3A4. Different CYP2C19 alleles have varying activity, which results in ultra-rapid, extensive, intermediate, and poor metabolizer genotypes.[208,209] Pharmacokinetics and pharmacodynamics vary among these different metabolizers.[210,211] Strong inhibitors of CYP3A4 have a minor effect on the pharmacokinetics of diazepam.[212,213] Inhibitors of CYP2C19 like omeprazole, fluvoxamine, and ciprofloxacin consequently increase the plasma half-life of diazepam substantially.[214-216] The clearance of lorazepam is affected by probenecid and valproic acid, both of which decrease the formation clearance of lorazepam-glucuronide.[217,218] Remimazolam is not metabolized by CYP-dependent mechanisms, which decreases the chances of significant drug interactions occurring.

PHARMACODYNAMIC DRUG INTERACTION

All benzodiazepines act on the CNS and interact with other drugs targeting the CNS, in particular those causing CNS depression.

In anesthetic practice, opioids are often combined with benzodiazepines, which interact in a synergistic manner.[219] The interaction between midazolam and ketamine is additive,[220] while the interaction between the hypnotic effects of thiopental and midazolam and of propofol and midazolam are synergistic.[20,221]

Uses

PREMEDICATION

Benzodiazepines are the most commonly applied drugs for premedication. The goals of this application are anxiolysis, sedation, amnesia, vagolysis, and sympathicolysis, and reduction of PONV.[222] The amnestic effects are anterograde; retrograde memory is not affected.

Diazepam, lorazepam, and midazolam are given orally or intravenously for preoperative sedation. Midazolam is the most frequently used benzodiazepine for premedication in both adults and children.[223] The usual oral dose for adults ranges from 7.5 to 15 mg for midazolam, from 5 to 10 mg for diazepam, and from 10 to 20 mg for temazepam.[224] Many factors like age, ASA physical status, level of anxiety, and type and length of surgery determine the dose. Lorazepam is mostly used when a prolonged and intense anxiolysis is pursued, like in cardiac surgery. Typically, 2 to 4 mg lorazepam is administered orally 2 hours before anesthesia and surgery.[225]

For pediatric patients midazolam is available in several preparations (including a formulation for intranasal administration in some countries) and well tolerated. The dose is effective from 0.025 mg/kg and produces sedation and anxiolysis in 10 to 20 minutes.

Midazolam has minimal effects on respiration and oxygen saturation in adults, even in doses up to 1.0 mg/kg with a maximum of 20 mg.

Sedation

Relief of anxiety and lack of recall of unpleasant events during minor surgical and diagnostic procedures are the primary objectives of good sedation. Appropriately used sedation improves patient satisfaction.[222] Patients are seemingly conscious and coherent during sedation with benzodiazepines, yet they are amnesic for the procedure and events.[226] For this use drugs should be given by titration; end points of titration are adequate sedation or dysarthria (Table 23.7). The onset of action is rapid with midazolam, usually with a peak effect reached within 2 to 3 minutes of administration; time to peak effect is slightly longer with diazepam and even longer still with lorazepam. The duration of action of these drugs are dose-dependent. Although the onset is more rapid with midazolam than with diazepam after bolus administration, the recovery is similar, probably because both drugs have similar early plasma decay (redistribution) patterns.[227] (also see Fig. 23.10). With lorazepam, sedation and particularly amnesia are slower in onset and are longer lasting than with the other two benzodiazepines.[228] Lorazepam is particularly unpredictable with regard to duration of amnesia, and this is undesirable in patients who wish or need to have recall in the immediate postoperative period. The degree of sedation, the reliable amnesia, and the preservation of respiratory and hemodynamic function are better with benzodiazepines than with other sedative-hypnotic drugs used for conscious sedation. When midazolam is compared with propofol for sedation during procedures, the two are generally similar except that emergence or wake-up is more rapid with propofol. Sedation with propofol is safe in the hands of well-trained non-anesthetic professionals.[229,230]

There are studies showing that remimazolam has a favorable profile as a sedative for upper gastrointestinal endoscopy in patients as the time to recovery was shorter and more consistent than that observed after the use of midazolam.[188,190] The use of midazolam for sedation during regional and epidural anesthesia requires vigilance with regard to depth of sedation and respiratory function.[231]

Two studies report the use of midazolam during cesarean section either for sedation in preeclamptic parturients or prevention of nausea and vomiting; they showed that a single IV dose of midazolam was a safe practice, with no detriment in Apgar scores, neurobehavioral scores, continuous oxygen saturation, or the ability of the mother to recall the birth events.[232] Nitsun and associates found that 0.005% of the maternal dose of midazolam is transferred into the breast milk during a 24-hour milk collection.[233] Although verification of these findings is needed, they highlight an important clinical use of midazolam that may be safe for mother and infant.

TABLE 23.7 Uses and Doses of Intravenous Benzodiazepines

	Midazolam	Diazepam	Lorazepam
Induction	0.05-0.15 mg/kg	0.3-0.5 mg/kg	0.1 mg/kg
Maintenance	0.05 mg/kg prn	0.1 mg/kg prn	0.02 mg/kg prn
	1 µg/kg/min

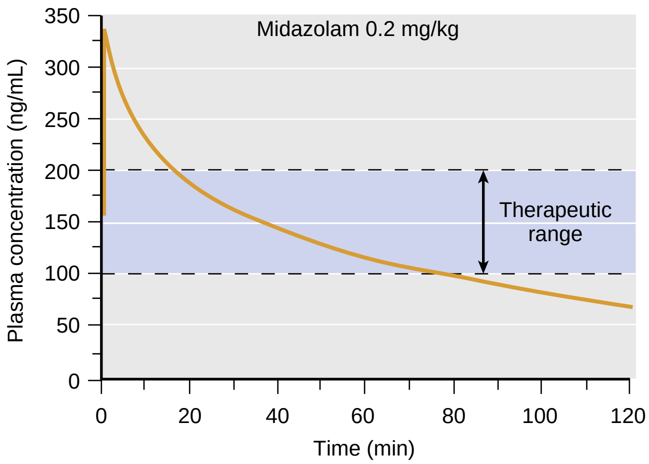

Fig. 23.10 Simulated time course of plasma levels of midazolam after an induction dose of 0.2 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 100 to 200 ng/mL, with awakening usually occurring at levels less than 50 ng/mL.

Sedation for longer periods, such as in the ICU, can also be accomplished with benzodiazepines. Prolonged infusion may result in accumulation of drug and, in the case of midazolam, significant concentration of the active metabolite. Reviews have pointed out both concerns and advantages of benzodiazepine sedation.[234] The main advantages are the amnesia and hemodynamic stability, where the disadvantage is the potential lingering sedative effect after termination of the infusion when compared with propofol and a higher prevalence of delirium compared to dexmedetomidine. In 2013, the Society of Critical Care Medicine's (SCCM) American College of Critical Care Medicine (ACCM) published a revised version of its pain, agitation, and delirium (PAD) clinical practice guidelines for adult ICU patients. These guidelines suggest that sedation strategies using non-benzodiazepine sedatives may be preferred over sedation with benzodiazepines, either midazolam or lorazepam, to improve clinical outcome in mechanically ventilated ICU patients.[235] To prevent overdosing and prolonged mechanical ventilation, evidence-based sedation algorithms have evolved. Daily interruption of sedation has not proven to decrease the time to extubation of the trachea or length of hospital stay.[236]

Induction and Maintenance of Anesthesia

Midazolam is the benzodiazepine of choice for induction of anesthesia. Numerous factors influence the rapidity of action of midazolam and the other benzodiazepines when used for induction of general anesthesia, including dose, speed of injection, degree of premedication, age, ASA physical status, and concurrent anesthetic drugs. The usual induction dose of midazolam is 0.1 to 0.2 mg/kg in premedicated patients, and up to 0.3 mg/kg in unpremedicated patients. The onset of anesthesia is within 30 to 60 seconds. The half-time of equilibrium between the plasma concentration and the EEG effects is about 2 to 3 minutes.[237]

Elderly patients require smaller doses of midazolam than younger patients (Fig. 23.11).[238]

When midazolam is combined with other anesthetic drugs (coinduction), often a synergistic interaction occurs, similar to that seen with propofol. This synergy is observed when midazolam is used with opioids or other hypnotics, similar to propofol in combination with opioids (Fig 23.12).[20,52,239]

Emergence time is related to the dose of midazolam and to the dose of adjuvant anesthetic drugs.

Benzodiazepines lack analgesic properties and must be used with other anesthetic drugs to provide sufficient analgesia; however, as maintenance anesthetic drugs during general anesthesia, benzodiazepines provide hypnosis and amnesia. The amnesic period after an anesthetic dose is about 1 to 2 hours.

A plasma level of more than 50 to 100 ng/mL occurs when used with adjuvant opioids (e.g., fentanyl) or inhaled anesthetics (e.g., nitrous oxide, volatile anesthetics) by a bolus initial dose of 0.05 to 0.15 mg/kg and a continuous infusion of 0.25 to 1 µg/kg/min.[240] This plasma level is sufficient to keep the patient asleep and amnesic but arousable at the end of surgery. Smaller infusion doses may be required in some patients or in combination with opioids. Midazolam, diazepam, and lorazepam accumulate in the blood after repeated bolus administrations or with continuous infusion. If the benzodiazepines do accumulate with repeated administration, prolonged arousal time can be anticipated. This is less of a problem with midazolam than with diazepam and lorazepam because of the shorter context-sensitive half-time and greater clearance of midazolam. Remimazolam might be a good alternative; it is rapidly metabolized and has a faster recovery profile than midazolam in sheep.[189,190]

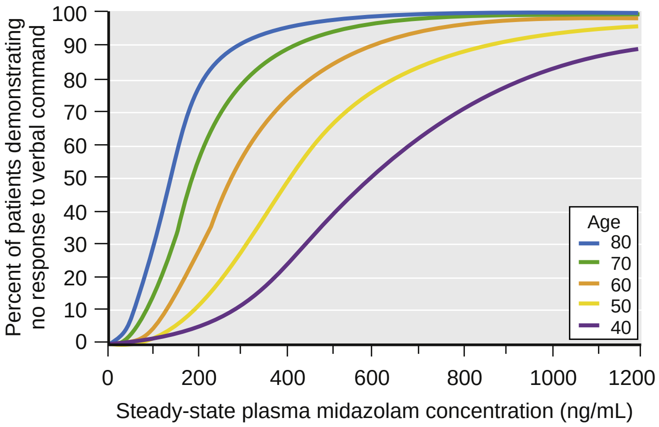

Fig. 23.11 Spectrum of the intrinsic activities of benzodiazepine receptor ligands, which range from agonists to inverse agonists. Structures of agonist, partial agonist, antagonist, partial inverse agonist, and inverse agonist compounds are shown. Intrinsic activity is greatest among agonists and is least among inverse agonists. Intrinsic activities are schematically indicated as positive by a plus sign and as negative by a minus sign, with 0 indicating a lack of intrinsic activity. *GABA*, γ-aminobutyric acid. (Redrawn with modification from Mohler H, Richards JG. The benzodiazepine receptor: a pharmacological control element of brain function. *Eur J Anaesthesiol.* 1988;Suppl 2:15–24.)

Nausea and Vomiting Prophylaxis

Numerous studies have highlighted the role that benzodiazepines, and specifically midazolam, may play in the prevention of PONV. A recent meta-analysis on the effect of intravenous midazolam on PONV concludes a significant decrease in overall PONV and rescue antiemetic drug. Jung and colleagues found that in women undergoing middle ear surgery, IV midazolam, 0.075 mg/kg after induction of anesthesia, reduced the incidence of PONV and the need for rescue antiemetics with no difference from placebo in pain intensity or drowsiness.[241] Furthermore, the combination of midazolam with dexamethasone proved more effective in preventing PONV than midazolam alone.[242] The incidence of PONV after minor gynecologic or urologic surgery was the same when comparing IV ondansetron, 4 mg, and IV midazolam, 2 mg.[243]

In children, IV midazolam, 0.05 mg/kg, reduced PONV significantly after pediatric (4-12 years old) strabismus surgery compared with placebo or IV dexamethasone 0.5 mg/kg. No child vomited with midazolam alone or with the midazolam dexamethasone combination.[244,245]

Finally, in a 2010 three-arm, placebo-controlled, double-blind clinical trial, Fuji and associates compared midazolam 0.050 mg/kg with 0.075 mg/kg in patients undergoing laparoscopic gynecologic surgery regarding PONV prophylaxis. The two doses of midazolam were not significantly different with regard to PONV (30% vs. 27% of patients experienced PONV) and both proved better than placebo (67%).[246]

Side Effects and Contraindications

Benzodiazepines have limited allergenic effects and do not suppress the adrenal gland. The most significant side effect with midazolam is respiratory depression. The major side effects of lorazepam and diazepam in addition to respiratory depression are venous irritation and thrombophlebitis, problems related to aqueous insolubility and requisite solvents.[165] When used as sedative or for induction and

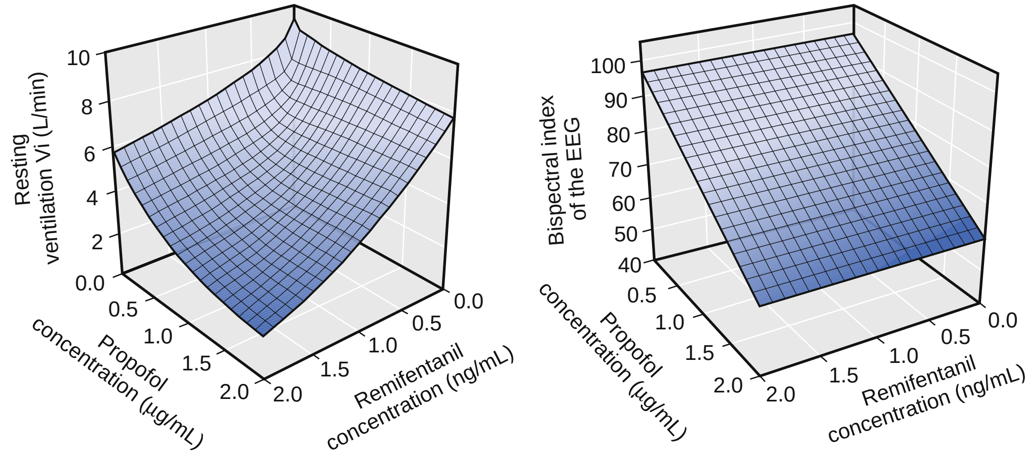

Fig. 23.12 Response surface modeling of the interaction of remifentanil and propofol on resting ventilation and the bispectral index of the electroencephalogram (BIS). Population response surface showing that the propofol–remifentanil interaction on respiration is synergistic and on BIS is inert since remifentanil had no effect on bispectral index irrespective of the propofol concentrations. Over this dose range, propofol causes a linear decrease in bispectral index with a 25% decrease occurring at 1.4 µg/mL. (From Nieuwenhuijs DJ, Olofsen E, Romberg RR, et al. Response surface modeling of remifentanil-propofol interaction on cardiorespiratory control and bispectral index. *Anesthesiology*. 2003; 98:312–322.)

maintenance of anesthesia, benzodiazepines may produce an undesirable degree or prolonged interval of postoperative amnesia, sedation, and, rarely, respiratory depression. These residual effects can be reversed with flumazenil.[247]

Flumazenil

Flumazenil (Anexate, Romazicon) is the first benzodiazepine antagonist approved for clinical use.[248] It is a benzodiazepine receptor ligand with high affinity, great specificity, and by definition minimal intrinsic effect. Flumazenil, similar to the agonists it replaces at the benzodiazepine receptor, interacts with the receptor in a concentration-dependent manner. It is a competitive antagonist at the benzodiazepine receptor and produces antagonism that is reversible and surmountable. In humans, flumazenil has minimal agonist activity, which means that its benzodiazepine receptor agonist effects are very weak, significantly less than those of clinical agonists.[249] Flumazenil, similar to all competitive antagonists at receptors, does not displace the agonist, but rather occupies the receptor when an agonist dissociates from the receptor. The half-time (or half-life) of a receptor-ligand bond is a few milliseconds to a few seconds, and new ligand receptor bonds are immediately formed. This dynamic situation accounts for the ability of either an agonist or an antagonist to readily occupy the receptor. The ratio of agonist to total receptors produces the effects of the agonist drug, but the antagonist can alter this ratio, depending on its concentration and dissociation constant. Flumazenil, which is an avid (high-affinity) ligand, replaces a relatively weak agonist, such as diazepam, as long as it is given in sufficient dose. Flumazenil is rapidly metabolically cleared, however, and the proportion of receptors occupied by the agonist then increases again, and the potential for rebound sedation and respiratory suppression exists (Fig. 23.13). This situation is less likely to occur when flumazenil is used to reverse midazolam, which has a more rapid clearance than other benzodiazepine agonists. Another important finding is that in the presence of extremely large doses of agonist (e.g., when a mistake in dosing has occurred, or suicide by means of an overdose is attempted), a small dose of flumazenil attenuates the deep CNS depression (loss of consciousness, respiratory depression) by reducing the fractional receptor occupancy by the agonist without decreasing the agonist effects that occur at low fractional receptor occupancy (drowsiness, amnesia).

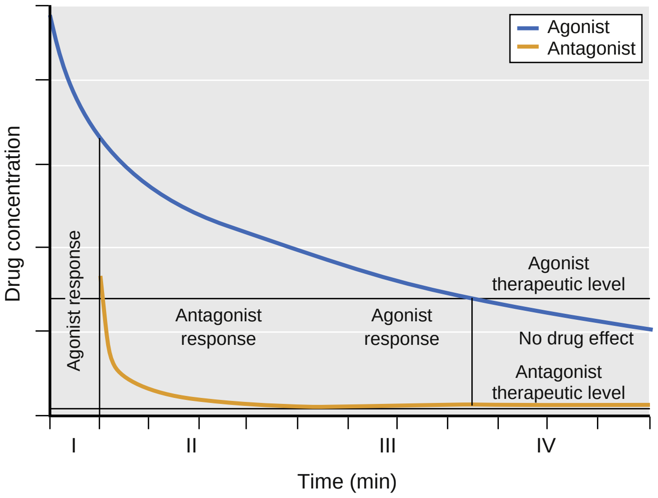

Fig. 23.13 Schematic representation of the interaction of a short-acting antagonist with a longer-acting agonist resulting in resedation. The upper curve shows disappearance of agonist from blood, and the lower curve shows disappearance of antagonist from plasma. Four conditions are represented: I, agonist response; II, antagonist response (the antagonist reverses the agonist effect); III, agonist response (resedation or resumption of agonist response with disappearance of short-lasting antagonist); and IV, no drug effect, with disappearance of agonist and antagonist (both drugs are below the therapeutic level).

Conversely, large doses of flumazenil in the presence of small doses of agonist completely reverse all the agonist effects. Flumazenil can precipitate withdrawal symptoms in animals or in humans physically dependent on a benzodiazepine receptor agonist.[250] However, this is not a problem when flumazenil is used to reverse clinical effects of benzodiazepine receptor agonists applied in the practice of anesthesia.

PHYSICOCHEMICAL CHARACTERISTICS

Flumazenil is similar to midazolam and other classic benzodiazepines except for the absence of the phenyl group, which is replaced by a carbonyl group (see Fig. 23.8). It forms a colorless, crystalline powder; has a dissociation constant of 1.7; and has weak but sufficient water solubility to permit its preparation in aqueous solution. Its octanol/aqueous buffer (pH 7.4) partition coefficient is 14, showing moderate lipid solubility at pH 7.4.[251]

PHARMACOKINETICS

Flumazenil, similar to the other benzodiazepines, is completely (99%) metabolized in the liver; is rapidly cleared from the plasma; and has three known metabolites: *N*-desmethylflumazenil, *N*-desmethylflumazenil acid, and flumazenil acid.[252] The metabolic end product, that is, flumazenil acid, has no pharmacologic activity. The major metabolites identified in urine are the de-ethylated free acid and its glucuronide conjugate. Flumazenil is a short-lived compound. Box 23.2 includes a summary of its pharmacokinetics, which are described in various clinical settings. The volume of distribution is high and extravascular distribution is rapid.

Compared with most benzodiazepine receptor agonists, flumazenil has a very rapid clearance and short elimination half-life.[253] Only remimazolam has a more rapid clearance and shorter half-life. The plasma half-life of flumazenil is

BOX 23.2 Uses and Doses of Flumazenil

Reversal of benzodiazepines	0.2 mg repeated up to 3 mg
Diagnosis in coma	0.5 mg repeated up to 1 mg

*The dose required to reverse each benzodiazepine (BZD) depends on residual BZD and the particular BZD (i.e., higher doses are required for more potent BZDs) (see text).

†The degree of reversal should be titrated by repeating 0.2-mg increments every 1 to 2 min until the desired level of reversal is achieved.

From Reves JG, Glass P, Lubarsky DA, et al. Intravenous anesthetics. In Miller RD, Eriksson LI, Fleischer LA, et al, eds. *Miller's Anesthesia,* 7th ed. Philadelphia: Churchill Livingstone; 2010: 719–768.

about 1 hour—it is the shortest lived of all benzodiazepines used in anesthetic practice. The rapid blood clearance of flumazenil approaches hepatic blood flow, a finding that indicates that liver clearance partially depends on hepatic blood flow. Compared with other benzodiazepines, flumazenil has a high proportion of unbound drug; plasma protein binding is about 40%. The potential exists for the antagonist to be cleared, leaving sufficient concentrations of agonist at the receptor site to cause resedation.[254] To maintain a constant therapeutic blood level over a prolonged time, either repeated administration or a continuous infusion is required. An infusion rate of 30 to 60 μg/min (0.5-1 μg/kg/min) has been used for this purpose.[255]

PHARMACODYNAMICS

When given in the absence of a benzodiazepine receptor agonist, flumazenil has little discernible CNS effect. When given to healthy subjects and patients in clinically relevant doses, flumazenil has no effect on the EEG or cerebral metabolism. Flumazenil is free of anticonvulsant properties, and reverses the anticonvulsant properties of benzodiazepines in local anesthetic-induced seizures.[256] When administered to patients who have benzodiazepine-induced CNS depression, flumazenil produces rapid and dependable reversal of unconsciousness, respiratory depression, sedation, amnesia, and psychomotor dysfunction.[257] Flumazenil can be given before, during, or after the agonist to block or reverse the CNS effects of the agonist.

Flumazenil has successfully reversed the effects of benzodiazepines like midazolam, diazepam, lorazepam, and flunitrazepam. It has also been used successfully to reverse the effects of chloralhydrate and cannabis intoxication in children, [258,259] carbamazepine and alcohol overdose,[260] and antihistamines overdose.[261] The onset is rapid, with peak effect occurring in 1 to 3 minutes, which coincides with the detection of C-flumazenil in the human brain.[257] Flumazenil reverses the agonist by replacing it at the benzodiazepine receptor, and its onset and duration are governed by the law of mass action. When flumazenil is given in the presence of agonists, there are significant respiratory effects because it reverses respiratory depression caused by the agonists (e.g., when given to volunteers made apneic with midazolam). For example, the reversal of midazolam-induced (0.13 mg/kg) respiratory depression with flumazenil (1 mg) lasts 3 to 30 minutes. Other agonists and other doses would have different durations of antagonism of respiratory depression.

Incremental doses up to 3 mg intravenously in patients with ischemic heart disease had no significant effect on cardiovascular variables.[257,262] Administration of flumazenil to patients given agonists is remarkably free of cardiovascular effects, in contrast to the experience of opioid reversal with naloxone.[263] Although flumazenil does reverse sedation, it does not increase blood concentrations of catecholamines. However, catecholamine levels may increase when arousal is more rapid after flumazenil.[264] The reversal of sedation by midazolam with flumazenil also restores the attenuated cardiac baroreflex function.[265]

In healthy subjects, flumazenil did not alter intraocular pressure but reversed the decrease in intraocular pressure observed after administration of midazolam (Romazicon package insert; www.fda.gov).

Uses and Doses

Application of a benzodiazepine antagonist (see Box 23.2) includes the diagnostic and therapeutic reversal of benzodiazepine receptor agonists. For diagnostic use in suspected benzodiazepine overdose, flumazenil may be given in incremental IV doses of 0.2 to 0.5 mg up to 3 mg. More commonly in anesthesia, flumazenil is used to reverse the residual sedation of a patient after administration of a benzodiazepine for premedication of a short surgical procedure, conscious sedation, or for general anesthesia. Flumazenil reliably reverses the sedation, respiratory depression, and amnesia caused by benzodiazepines. There are differential reversal effects on the different agonist actions. Flumazenil tends to reverse the hypnotic and respiratory effects more than the amnesic effects of the benzodiazepine agonist.[266,267]

The dose varies with the particular benzodiazepine being reversed, and the duration of reversal depends on the kinetics of the agonist and of flumazenil. Surveillance is recommended if a long-lasting benzodiazepine is reversed with a single administration of flumazenil because of the relatively short-lived effect. If a patient shows no signs of recurrent sedation within 2 hours after a 1-mg reversal dose of flumazenil, serious recurrent sedation at a later time is unlikely. Flumazenil may be administered by continuous infusion to prevent recurrent sedation by longer lasting benzodiazepine receptor agonists. The pharmacokinetic profile of flumazenil is unaltered in the presence of benzodiazepine agonists (diazepam, flunitrazepam, lormetazepam, midazolam) and vice versa.

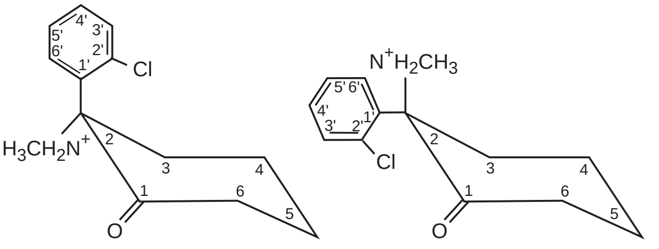
Side Effects and Contraindications

Flumazenil has been given in large oral and IV doses with remarkably few toxic reactions.[257] It is free of local or tissue irritant properties, and there are no known organotoxicities. Similar to all benzodiazepines, it apparently has a high safety margin, probably higher than the safety margins of the agonists, because it does not produce prominent CNS depression. In patients using large doses of benzodiazepines over several weeks or longer, the administration of flumazenil may elicit symptoms of benzodiazepine withdrawal, including seizures.

Phencyclidines (Ketamine)

HISTORY

Ketamine (Ketalar) was synthesized in 1962 by Stevens and was first used in humans in 1965 by Corssen and Domino. Ketamine was released for clinical use in 1970 and is still used in various clinical settings. It produces dissociative anesthesia rather than generalized depression of the CNS through antagonistic actions at the phencyclidine (PCP) site of the N-methyl-D-aspartate receptor (NMDAR). Ketamine is a racemic mixture of the isomers R(-)-ketamine and S(+)-ketamine. It usually does not depress the cardiovascular and respiratory systems, but it does possess some of the adverse psychological effects found with the other phencyclidines.[268] The S(+)-isomer (Ketanest) is 3 to 4 times more potent as an analgesic with a faster clearance and recovery and with fewer psychomimetic side effects. Still, S-ketamine produces—besides analgesia—psychotropic effects, cognitive impairment, memory impairment, and a reduced



S_1(+) Ketamine hydrochloride R_1(–) Ketamine hydrochloride

Fig. 23.14 Stereoisomers of ketamine as it is formulated.

reaction time. Interest in ketamine has increased more recently because of its effects on hyperalgesia and opiate tolerance, use in chronic pain states, potential neuroprotective effects, increasing popularity of total IV anesthesia, and the availability in some countries of S(+) ketamine.[269] Lastly, ketamine receives growing interest because of its antidepressant effects.

PHYSICOCHEMICAL CHARACTERISTICS

Ketamine (Fig. 23.14) has a molecular weight of 238 kD, is partially water soluble, and forms a white crystalline salt with a pK_a of 7.5. It has a lipid solubility 5 to 10 times that of thiopental. Ketamine is only 12% bound to proteins. Its bioavailability is 93% after parenteral administration but only 20% after oral use, due to its high first-pass metabolism.[270]

PHARMACOKINETICS

Ketamine is metabolized by hepatic microsomal enzymes.[271,272] The major pathway involves *N*-demethylation to form norketamine (metabolite I), which is then hydroxylated to hydroxynorketamine, which is further conjugated to water-soluble glucuronide derivates and excreted in the urine. The activity of the principal metabolites of ketamine has not been well studied, but norketamine (metabolite I) has significantly less (20%-30%) activity than the parent compound. More recent modeling of norketamine suggests that it contributes in prolonging the analgesia provided by either a bolus or infusion of ketamine, although this conclusion is being questioned.[271,273,274] In contrast to previous reports, S-norketamine may have a negative contribution to S-ketamine-induced analgesia but shows absence of contribution to the cognitive impairment. This may explain the observation of ketamine-related excitatory phenomena (such as hyperalgesia and allodynia) upon the termination of ketamine infusions.[271,273,274]

Ketamine's pharmacokinetics have been examined after bolus administration of anesthetizing doses (2-2.5 mg/kg IV), after a subanesthetic dose (0.25 mg/kg IV), and after continuous infusion (steady-state plasma level 2000 ng/mL).

Regardless of the dose, ketamine plasma disappearance can be described by a two-compartment model. Table 23.1 contains the pharmacokinetic values from bolus administration studies. Of note is the rapid distribution reflected in the relatively brief distribution half-life of 11 to 16 minutes (Fig. 23.15). The high lipid solubility of ketamine is reflected in its large volume of distribution of nearly 3 L/kg.[272,275] Clearance also is high, 890 to 1227 mL/min, which accounts for the short elimination half-life of 2 to 3 hours. The mean total body clearance (1.4 L/min) is approximately equal to liver blood flow. Low-dose alfentanil increases the volume of distribution and clearance of ketamine. In addition, alfentanil increases the distribution of ketamine into the brain. The pharmacokinetic model of Clements provided the best accuracy when used to administer low-dose ketamine to volunteers using a target-controlled infusion device. The pharmacokinetics of the two isomers is different. S(+) ketamine has a larger elimination clearance and larger volume of distribution than R(−) ketamine. When the pharmacokinetics of S(+) ketamine were tested in a target-controlled infusion device for procedures of 1 hour and in combination with propofol, the authors found that the accuracy of the pharmacokinetic parameters was improved with a much smaller Vc[*] (167 mL/kg).[276] They also noted that ketamine clearance was not normally distributed, and this was not related to age. The S(+) enantiomer also seems to be more potent in suppressing the EEG than either R(−) or the racemic mixture. Ketamine is increasingly being given by alternative routes, especially orally and via an intranasal spray. Administration by either of these routes is subject to significant first-pass metabolism. The bioavailability via oral administration is 20% to 30%, and via the intranasal route is approximately 40% to 50%. In clinical and experimental studies hyperalgesic responses have been noted after the withdrawal of *S*(+)-ketamine.[273-275,277,278] Furthermore, no delay between concentration and effect has been observed for any of the antinociceptive end points. This indicates an almost immediate passage of S(+)-ketamine across the blood-brain barrier and rapid receptor kinetics.

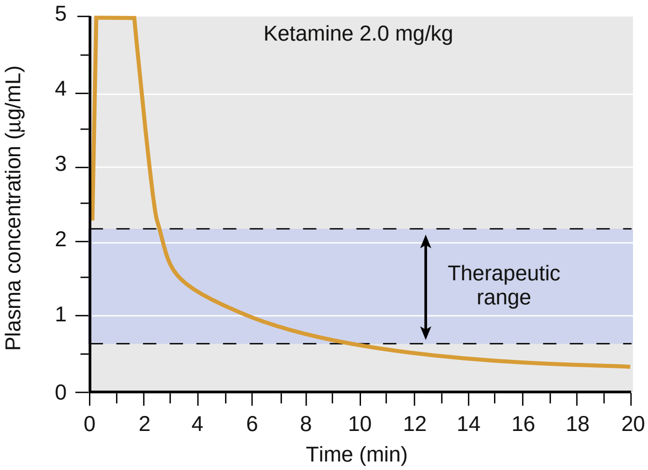


Fig. 23.15 Simulated time course of plasma levels of ketamine after an induction dose of 2 mg/kg. Plasma levels required for hypnosis and amnesia during surgery are 0.7 to 2.2 μg/mL, with awakening usually occurring at levels less than 0.5 μg/mL.

Pharmacodynamics

EFFECTS ON THE CENTRAL NERVOUS SYSTEM

Ketamine produces dose-related unconsciousness and analgesia. Ketamine acts at multiple receptors including the NMDAR, opioid receptors, and monoaminergic receptors.

---

[*] Vc (central compartment volume of a three compartment model).

At high ketamine concentrations, sigma opioid receptors are also affected, muscarinic receptors are blocked, and GABAergic neurotransmission is facilitated. Its most important action is the inhibition of NMDAR-mediated glutamergic input to the GABAergic system leading to a changing excitatory activity in the cortex and limbic system that in the end results in unconsciousness. At the spinal cord level, ketamine has potent antinociceptive effects on NMDAR and inhibits acetylcholine release.[273-275] The anesthetized state has been termed *dissociative anesthesia* because patients who receive ketamine alone appear to be in a cataleptic state, in contrast with other states of anesthesia that resemble normal sleep. Patients anesthetized with ketamine have profound analgesia, but keep their eyes open and maintain many reflexes. Corneal, cough, and swallow reflexes all may be present, but should not be assumed to be protective. There is no recall of surgery or anesthesia, but amnesia is not as prominent with ketamine as with the benzodiazepines. Because ketamine has a low molecular weight, a pK_a near the physiologic pH, and relatively high lipid solubility, it crosses the blood-brain barrier rapidly and has an onset of action within 30 to 60 seconds of administration. The maximal effect occurs in about 1 minute.

After ketamine administration, pupils dilate moderately, and nystagmus occurs. Lacrimation and salivation are common, as is increased skeletal muscle tone, often with coordinated but seemingly purposeless movements of the arms, legs, trunk, and head. Although there is great inter-individual variability, plasma levels of 0.6 to 2 μg/mL are considered the minimum concentrations for general anesthesia; children may require slightly higher plasma levels (0.8-4 μg/mL). The duration of ketamine anesthesia after a single IV administration of a general anesthetic dose (2 mg/kg) is 10 to 15 minutes (see Fig. 23.15), and full orientation to person, place, and time occurs within 15 to 30 minutes. The S(+) enantiomer enables quicker recovery (by a couple of minutes) than the racemic mixture.[279,280] This is due to the smaller dose necessary to produce an equi-anesthetic effect and to the 10% faster hepatic biotransformation. Because there is a good correlation between blood concentration of ketamine and CNS effect, the relatively short duration of action of ketamine is probably due to its redistribution from the brain and blood to the other tissues in the body.

Concomitant administration of benzodiazepines, which is a common practice, may prolong the effect of ketamine. When used in combination with a benzodiazepine, the S(+) enantiomer was no different in terms of awareness at 30 minutes, but it was significantly better at 120 minutes than the racemic mixture. Analgesia occurs at considerably lower blood concentrations than loss of consciousness.

Ketamine provides important postoperative analgesia. The plasma level at which pain thresholds are elevated is 0.1 μg/mL or greater.[277,281,282] This means there is a considerable period of postoperative analgesia after ketamine general anesthesia, and subanesthetic doses can consequently be used to produce analgesia. Ketamine inhibits nociceptive central hypersensitization. Ketamine also attenuates acute tolerance after opiate administration. The NMDAR plays an important role in the induction of hyperalgesia and antinociceptive tolerance as induced by opioids. Preventive ketamine administration may thus prevent central sensitization and long-lasting enhancement in pain sensitivity as induced by opioids. Ketamine, just as other NMDAR antagonists, may thus prevent opioid-induced hyperalgesia.[283] The primary site of CNS action of ketamine seems to be the thalamoneocortical projection system. The drug selectively depresses neuronal function in parts of the cortex (especially association areas) and thalamus, while stimulating parts of the limbic system, including the hippocampus. This process creates what is termed a *functional disorganization* of nonspecific pathways in midbrain and thalamic areas. Ketamine acts via antagonism of the excitatory glutamatergic NMDA receptor. The NMDA receptor has a high expression in the temporal cortex, hippocampus, basal ganglia, cerebellum, and brainstem, all regions significantly affected by ketamine. There is also evidence that ketamine depresses transmission of impulses in the medial medullary reticular formation, which is important for transmission of the affective-emotional components of nociception from the spinal cord to higher brain centers. In volunteers experiencing heat pain, functional magnetic resonance imaging (MRI) studies showed ketamine produced a dose-dependent effect on pain processing by decreasing activation of the secondary somatosensory cortex (S2), insula, and anterior cingulate cortex. Ketamine occupies opiate receptors in the brain and spinal cord, and this property could account for some of the analgesic effects.[284,285] The S(+) enantiomer has some opioid μ-receptor activity, accounting for part of its analgesic effect. NMDA receptor interaction may mediate the general anesthetic effects and some analgesic actions of ketamine. The spinal cord analgesic effect of ketamine is postulated to be due to inhibition of dorsal horn wide dynamic range neuronal activity. In a resting state fMRI study, low-dose ketamine induced connectivity changes in brain areas involved in motor function, psychedelic effects, and pain processing. Ketamine's analgesic effect may arise from multiple pathways; a decreased connectivity in regions of the pain matrix responsible for the perception of pain (pain sensing) and the affective processing of pain. In addition, ketamine affected connectivity in brain areas involved in endogenous pain inhibition.[286,287]

Although some drugs have been used to antagonize ketamine, no specific receptor antagonist reverses all the CNS effects of ketamine.

Ketamine increases cerebral metabolism, CBF, and ICP. Because of its excitatory CNS effects, which can be detected by generalized EEG development of theta wave activity and by petit mal seizure-like activity in the hippocampus, ketamine increases $CMRO_2$. There is an increase in CBF, which appears higher than the increase in $CMRO_2$ would mandate. With the increase in CBF and the generalized increase in sympathetic nervous system response, there is an increase in ICP after ketamine. The increase in $CMRO_2$ and CBF can be blocked by the use of thiopental or diazepam. Cerebrovascular responsiveness to carbon dioxide seems to be preserved with ketamine; reducing $PaCO_2$ attenuates the increase in ICP after ketamine.

S(+) ketamine may influence the expression of apoptosis-regulating proteins in rat brains 4 hours after cerebral ischemia/reperfusion. The neuroprotection observed with ketamine may involve antiapoptotic mechanisms in addition to reducing necrotic cell death.

In contrast, ketamine and other anesthetics like propofol and volatile anesthetics, accentuate apoptosis in the brain of newborn animals and cause changes in the morphology of dendritic spines. This finding has sparked controversy over the use of ketamine in neonates. An editorial in the journal *Anesthesiology* and the Anesthetic and Life Support Drugs Advisory Committee of the FDA cautioned changing clinical practice based on present available data.

Ketamine, similar to other phencyclidines, produces undesirable psychological reactions, which occur during awakening from ketamine anesthesia and are termed *emergence reactions*. The common manifestations of these reactions, which vary in severity and classification, are vivid dreaming, extracorporeal experiences (sense of floating out of body), and illusions (misinterpretation of a real, external sensory experience). These incidents of dreaming and illusion are often associated with excitement, confusion, euphoria, and fear. They occur in the first hour of emergence and usually abate within 1 to several hours. The psychic emergence reactions occur secondary to ketamine-induced depression of auditory and visual relay nuclei, leading to misperception or misinterpretation of auditory and visual stimuli. The incidence of the psychic emergence reactions ranges from 3% to 100%. A clinically relevant range is probably 10% to 30% of adult patients who receive ketamine as a sole or major part of the anesthetic technique. Factors that affect the incidence of emergence reactions are age, dose, gender, psychological susceptibility, and concurrent drugs. Pediatric patients do not report as high an incidence of unpleasant emergence reactions as do adult patients; men also report a less frequent incidence compared with women. Larger doses and rapid administration of large doses seem to predispose patients to a frequent incidence of adverse effects. Finally, certain personality types seem prone to the development of emergence reactions. Patients who score high in psychotism on the Eysenck Personality Inventory are prone to develop emergence reactions, and individuals who commonly dream at home are more likely to have postoperative dreams in the hospital after ketamine. While numerous drugs have been used to reduce the incidence and severity of postoperative reactions to ketamine, the benzodiazepines seem to be the most effective group of drugs. Next to the undesirable psychological reactions, increasingly ketamine is described for its antidepressant effects. The dose often used for this indication is 0.5 mg/kg, given as a 40-minute infusion. This often results in a dramatic mood change within a day, often lasting for 3 to 12 days. A maintenance dose every 2 to 4 days may lengthen this effect.[288] The precise mechanism of action of the antidepressant effects of ketamine remain unknown.

EFFECTS ON THE RESPIRATORY SYSTEM

Ketamine has minimal effects on the central respiratory drive as reflected by an unaltered response to carbon dioxide. There can be a transient (1-3 minutes) decrease in minute ventilation after the bolus administration of an induction dose of ketamine (2 mg/kg intravenously). Unusually large doses can produce apnea, but this is seldom seen. In a μ-opioid knockout mouse model, though, at supraspinal sites S(+) ketamine interacts with the μ-opioid receptor system. This interaction contributes significantly to S(+) ketamine-induced respiratory depression and supraspinal antinociception.[289,290] With the use of adjuvant sedatives or anesthetic drugs, respiratory depression may become clinically significant. Ketamine depresses ventilatory control in children especially with bolus doses. Ketamine is a bronchial smooth muscle relaxant. When it is given to patients with reactive airway disease and bronchospasm, pulmonary compliance is improved.

Ketamine is as effective as halothane or enflurane in preventing experimentally induced bronchospasm. The mechanism for this effect is probably a result of the sympathomimetic response to ketamine, but there are isolated bronchial smooth muscle studies showing that ketamine can directly antagonize the spasmogenic effects of carbachol and histamine. Owing to its bronchodilating effect, administration of ketamine can treat status asthmaticus unresponsive to conventional therapy. A potential respiratory problem, especially in children, is the increased salivation that follows ketamine administration, which can be modulated by an anticholinergic drug such as atropine or glycopyrolate.

EFFECTS ON THE CARDIOVASCULAR SYSTEM

Ketamine increases arterial blood pressure, heart rate, and cardiac output in a biphasic manner. It produces a direct cardiodepressive, negative inotropic effect next to an indirect stimulatory effect due to activation of the sympathetic system. Ketamine causes the systemic release of catecholamines, inhibition of the vagal nerve, inhibition of norepinephrine reuptake at peripheral nerves and non-neuronal tissues such as the myocardium, and norepinephrine release from sympathetic ganglia.[291] Cardiodepression precedes stimulation after large-dose ketamine administration or occurs after repeated administrations when presynaptic catecholamine stores become depleted. Cardiovascular stimulation already occurs after small-dose ketamine infusion and is characterized by tachycardia, systemic and pulmonary hypertension, increases in cardiac output, and myocardial oxygen consumption. Whereas the cardiovascular stimulatory effects of ketamine generally are dominant, after termination of S-ketamine infusion, cardiovascular depression may become evident as cardiac output may decrease below pre-infusion values.[273] The cardiovascular stimulatory effects of S(+) ketamine are characterized by an increase in the cardiac output of 1 L/min in the presence of 243 ng/ml S(+) ketamine.[273] The cardiovascular stimulatory effect of S(+) ketamine is induced very rapidly with a half-life for onset/offset of the effect of ketamine on cardiac output of 1 to 2 minutes. The increase in hemodynamic variables is associated with increased work and myocardial oxygen consumption. The healthy heart increases oxygen supply by increased cardiac output and decreased coronary vascular resistance, so that coronary blood flow is appropriate for the increased oxygen consumption. In patients with congenital heart disease, there are no significant changes in shunt directions or fraction, or systemic oxygenation after ketamine induction of anesthesia. In patients who have increased pulmonary artery pressure (as with mitral valvular and some congenital lesions), ketamine causes a more pronounced increase in pulmonary than systemic vascular resistance. Ketamine injected directly into the CNS produces an immediate sympathetic nervous system hemodynamic response. Ketamine also causes the sympathoneuronal release of norepinephrine, which can be detected in venous blood. Blockade of this effect is possible with barbiturates, benzodiazepines, and droperidol. The centrally mediated sympathetic responses to ketamine usually override the direct depressant effects of ketamine. Some peripheral nervous system actions of ketamine play an undetermined role in the hemodynamic effects of the drug. Ketamine inhibits intraneuronal uptake of catecholamines in a cocaine-like effect and inhibits extraneuronal norepinephrine uptake.

Stimulation of the cardiovascular system is not always desirable, and certain pharmacologic methods have been used to block the ketamine-induced tachycardia and systemic hypertension. Probably the most fruitful approach has been prior administration of benzodiazepines. Modest doses of diazepam, flunitrazepam, and midazolam all attenuate the hemodynamic effects of ketamine. It also is possible to decrease the tachycardia and hypertension caused by ketamine by using a continuous infusion technique with or without a benzodiazepine. Inhalation anesthetics and propofol blunt the hemodynamic effect of ketamine.

Uses

The many unique features of ketamine pharmacology, especially its propensity to produce unwanted emergence reactions in 10% to 20% of patients, have limited its use for routine anesthesia. Nevertheless, ketamine has an important niche in the practice of anesthesiology when its unique sympathomimetic activity and bronchodilating capabilities are indicated during induction of anesthesia. It is used for premedication, sedation, induction, and maintenance of general anesthesia. There has been increased interest in the use of ketamine in small doses for preventive analgesia, for the treatment or prevention of opiate tolerance and hyperalgesia, and in treatment of acute and chronic pain.

Induction and Maintenance of Anesthesia

The cardiovascular stimulatory effects make ketamine a desirable drug for the induction of anesthesia in unstable cardiovascular patients suffering from hypovolemia, hemorrhagic shock, or cardiovascular depression in sepsis. Ketamine bronchodilation and profound analgesia allowing the use of high oxygen concentrations make ketamine an excellent choice for induction of anesthesia in patients with reactive airway disease. Trauma patients with extensive blood loss are typical candidates for rapid-sequence anesthesia induction with ketamine. Patients with septic shock also may benefit from ketamine. The intrinsic myocardial depressant effect of ketamine may manifest in this situation if trauma or sepsis has caused depletion of catecholamine stores before the patient's arrival in the operating room. Use of ketamine in these patients does not obviate the need for appropriate preoperative preparation, including restoration of intravascular blood volume. Other cardiac diseases that can be well managed with ketamine anesthesia are cardiac tamponade and restrictive pericarditis. The finding that ketamine preserves heart rate and right atrial pressure through its sympathetic stimulating effects makes ketamine an excellent anesthetic induction and maintenance drug in this setting. Ketamine also is often used in patients with congenital heart disease, especially patients in whom the propensity for right-to-left shunting exists. Ketamine has been successfully used in a patient susceptible to malignant hyperthermia. Ketamine combined with propofol or midazolam can be given by continuous infusion to produce satisfactory cardiac anesthesia for patients with valvular and ischemic heart disease. The combination of a benzodiazepine or of a benzodiazepine plus sufentanil with ketamine attenuates or eliminates the unwanted tachycardia and hypertension and postoperative psychological derangements. With this technique, there are minimal hemodynamic perturbations, profound analgesia, dependable amnesia, and an uneventful convalescence. The use of propofol plus small-dose ketamine also has gained increasing popularity as a total IV anesthesia technique for patients undergoing noncardiac surgery. The advantages of this combination are maintenance of stable hemodynamics and minimal ventilatory depression when allowing spontaneous ventilation.

Pain Management

Postoperative pain is a major concern of many patients and inadequately treated in as many as 30% to 50% of all postoperative patients. Multimodal analgesia combining various analgesic agents that act through different pathways is the way to manage postoperative pain. Ketamine is increasingly used as one of the constituents of this multimodal analgesia therapy. Over the years the ketamine dose used for perioperative analgesia has gradually been decreasing. Ketamine administered in small doses decreases postoperative analgesic consumption by 33%. Several meta-analyses of the use of small-dose ketamine (20 to 60 mg) perioperatively have been performed. These meta-analyses showed an overall decrease in opiate use or improved analgesia and a decrease in opiate-induced side effects, especially PONV. Side effects, especially psychomimetic effects, were minimal, especially if a benzodiazepine also was administered.

The epidural/caudal administration of ketamine (0.5 to 1 mg/kg) is effective. Although the efficacy of these doses of ketamine seems to be established, the safety of this technique has not yet received regulatory approval. The preservative of racemic mixture is potentially neurotoxic, whereas studies to date indicate preservative-free S(+) ketamine may be safe. Epidural preservative-free S(+) ketamine has been shown to be safe and of value in adjunct to corticosteroids in patients for the treatment of chronic low back pain secondary to radiculopathy.[292] The favorable hemodynamic effects and conservation of respiration makes intravenously and even intranasally administered ketamine useful for analgesia after extremity fractures.

The action of ketamine on opiate tolerance and hyperalgesia combined with its direct analgesic activity has led to its use in chronic pain states. Ketamine may be effective in the treatment of cancer pain, chronic peripheral and central neuropathic pain, phantom and ischemic limb pain, fibromyalgia, complex regional pain syndrome, visceral pain, and migraine. Multiple open-label studies conclude positively on the analgesic properties of ketamine in cancer pain. Randomized controlled trials, though, so far could not prove a clinical benefit of ketamine for this indication.[293] Thus, while ketamine is effective for relief of postoperative pain, causing reduced opioid consumption, ketamine for most other indications appears to have limited efficacy and results in no beneficial effects.

BOX 23.3 Uses and Doses of Ketamine

Induction of general anesthesia*	0.5-2 mg/kg IV 4-6 mg/kg IM
Maintenance of general anesthesia	0.5-1 mg/kg IV with N_2O 50% in O_2 15-45 μg/kg/min IV with N_2O 50%-70% in O_2 30-90 μg/kg/min IV without N_2O
Sedation and analgesia	0.2-0.8 mg/kg IV over 2-3 min 2-4 mg/kg IM
Preemptive or preventive analgesia	0.15-0.25 mg/kg IV

*Lower doses are used if adjuvant drugs such as midazolam or thiopental also are given. *IM,* Intramuscular; *IV,* intravenous; *N_2O,* nitrous oxide.

Sedation

Often, ketamine is combined with premedication of a barbiturate or benzodiazepine and an antisialagogue (e.g., glycopyrrolate) to facilitate management. The premedications reduce the dose requirement for ketamine, and the antisialagogue reduces the sometimes troublesome salivation. In adults and children, ketamine can be used as a supplement or an adjunct to regional anesthesia, extending the usefulness of the primary (local anesthetic) form of anesthesia. Also, in the emergency department ketamine is increasingly used for short painful procedures. The dose used then is between 0.1 to 0.6 mg/kg. As previously described, ketamine also may be considered for sedation of patients in a critical care unit because of its combined sedative and analgesic properties and favorable effects on hemodynamics. Ketamine can even be used safely in head injury patients when they are adequately ventilated.[294,295]

Ketamine is particularly suitable for sedation of pediatric patients undergoing procedures outside of the operating room. Pediatric patients have fewer adverse emergence reactions than adults, and this feature makes the use of ketamine in pediatric patients more versatile.

Doses and Routes of Administration

Ketamine has been administered intravenously, intramuscularly, transcutaneously, orally, nasally, and rectally, and as a preservative-free solution epidurally or intrathecally. Most clinical use involves the IV and intramuscular (IM) routes, by which the drug rapidly achieves therapeutic concentrations. The dose depends on the desired therapeutic effect and on the route of administration. Box 23.3 contains general recommended doses for the IV and IM administration of ketamine for various therapeutic goals. Intranasal administration has an onset closer to IV administration; an oral dose of 3 to 10 mg/kg generates a sedative effect in 20 to 45 minutes. For sedation, ketamine may be given in an IM dose of 2 to 4 mg/kg. It also has been administered orally in doses of 3 to 10 mg/kg, with 6 mg/kg providing optimal conditions in 20 to 25 minutes in one study and 10 mg/kg providing sedation in 87% of children within 45 minutes in another study.

Side Effects and Contraindications

Contraindications to ketamine relate to specific pharmacologic actions and patient diseases. In patients with increased ICP and breathing spontaneously, ketamine should be used with caution because it can increase ICP and has been reported to cause apnea. There is increasing clinical use of ketamine in emergency airway management in brain injury patients with or without other body injuries. In this setting, the current knowledge on safe management of increased ICP is continuing to grow.[294,295]

In mechanically ventilated patients, ketamine retains the response of CBF to carbon dioxide, which makes it useful in head-injured patients because of its potential neuroprotective effect. Ketamine may be contraindicated in patients with an open eye injury or other ophthalmologic disorder, in which a ketamine induced increase in intraocular pressure would be detrimental. Because ketamine has a propensity to cause hypertension and tachycardia, with a commensurate increase in myocardial oxygen consumption, it may be contraindicated as the sole anesthetic in patients with ischemic heart disease. Likewise, it is unwise to give ketamine to patients with vascular aneurysms because of the possible sudden change in arterial blood pressure. Psychiatric disease, such as schizophrenia, and a history of adverse reaction to ketamine or one of its congeners also are contraindications. One also should consider carefully using ketamine when there is a possibility of postoperative delirium from other causes (e.g., delirium tremens, possibility of head trauma), and a ketamine-induced psychomimetic effect would confuse the differential diagnosis.

As mentioned earlier, ketamine or other NMDA receptor antagonists accentuate apoptosis in the newborn brain of animals, and the clinical implications of this are unknown. Finally, because ketamine's preservative—chlorobutanol—is neurotoxic, this formulation of ketamine for subarachnoid or epidural administration is contraindicated. S(+) ketamine is available in a preservative-free solution. The FDA has not approved the use of intrathecal or epidural ketamine. Caudal ketamine has been used for perioperative analgesia in children and neonates with 0.5 mg/kg as the optimal dose. Caudal analgesia, by combinations of ketamine and a local anesthetic, prolongs analgesia from 2.26 to 5.3 hours and reduces the need for nonopioid analgesics.[296-300]

Lastly, liver and renal toxicity occurs in the recreational abuse of ketamine. In addition, when ketamine is repeatedly administered in the treatment of chronic pain in patients with complex regional pain syndrome type 1 (CRPS), hepatotoxicity developed in patients that received two 100-hour infusions of S(+)-ketamine with a 16-day interval.[298,301,302]

Etomidate

HISTORY

The first report on etomidate was published in 1965.[303] Etomidate was introduced into clinical practice in 1972. The unique properties of etomidate include hemodynamic stability, minimal respiratory depression, cerebral protection, favorable toxicity profile, and pharmacokinetics enabling rapid recovery after either a single dose or a continuous infusion. In the 1970s, these beneficial properties led to widespread use of etomidate for induction, for maintenance of anesthesia, and for prolonged sedation in critically

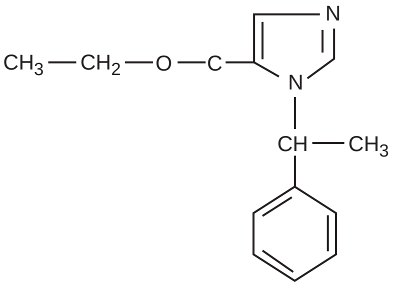

Fig. 23.16 **Structure of etomidate, an imidazole derivative.**

ill patients. The enthusiasm among clinicians for etomidate was tempered in the 1980s by reports that the drug can cause temporary inhibition of steroid synthesis after single doses and infusions.[304,305] This effect, combined with other minor disadvantages (e.g., pain on injection, superficial thrombophlebitis, myoclonus, and a frequent incidence of nausea and vomiting), led to several editorials questioning the role of etomidate in modern anesthetic practice.[306,307] Use of the drug decreased after those editorials, but its use has expanded again as a result of the rediscovery of etomidate's beneficial physiologic profile and a widening use in emergency departments and intensive care departments, combined with a lack of novel reports describing clinically significant adrenocortical suppression after induction or brief duration infusions.

PHYSICOCHEMICAL CHARACTERISTICS

Etomidate is an imidazole derivative (R-(+)-pentylethyl-1H-imidazole-5 carboxylate sulfate). Its chemical structure is illustrated in Fig. 23.16. Etomidate has a pK_a of 4.2 and is hydrophobic at physiologic pH. To increase its solubility it is formulated as a 0.2% solution either in 35% propylene glycol (Amidate; Hospira Inc., Lafe Forest, IL) or in a lipid emulsion (Etomidate-Lipuro; B. Braun, Melsungen, Germany).[308]

PHARMACOKINETICS

The pharmacokinetics of etomidate have been determined after single bolus doses and after continuous infusion. The time course of plasma disappearance after a 0.3 mg/kg bolus is shown in Fig. 23.17. The pharmacokinetics of etomidate are best described by an open three-compartment model.[309]

The drug has an initial distribution half-life of 2.7 minutes, a redistribution half-life of 29 minutes, and an elimination half-life of 2.9 to 5.3 hours.[310] Clearance of etomidate by the liver is high (18-25 mL/kg/min), with a hepatic extraction ratio of 0.5 ± 0.9.[309] Because redistribution is the mechanism whereby the effect after a bolus of etomidate is dissipated (Box 23.4), hepatic dysfunction should not appreciably alter recovery from a single induction dose. Etomidate is 75% protein bound.

A hemorrhagic shock model in pigs bled to a MAP of 50 mm Hg did not alter etomidate pharmacokinetics or pharmacodynamics.[311] This finding contrasts with the marked changes seen in this same model with other IV anesthetics. In patients with cirrhosis, the volume of distribution is doubled, whereas clearance is normal; the result is an elimination half-life that is twice normal.[312] The initial distribution half-life and clinical effect are likely unchanged. Increasing age is associated with a smaller initial volume of distribution and a decreased clearance of etomidate.[313]

The short elimination half-life and the rapid clearance of etomidate make it suitable for administration in a single dose, in multiple doses, or in a continuous infusion with its context sensitive half-time being shorter than that of propofol.[314] Continuous infusion was practiced in the first decade of its clinical availability, but the now widely recognized adrenal suppression limits this application. Etomidate is metabolized in the liver primarily by ester hydrolysis to the corresponding carboxylic acid of etomidate (major metabolite) and an ethanol leaving group.[315] The main metabolite is inactive. Only 2% of the drug is excreted unchanged, the remaining part being excreted as metabolites by the kidney (85%) and bile (13%). Pathologic conditions altering serum proteins (e.g., hepatic or renal disease) affect the amount of the free (unbound) fraction and may cause a dose to have an exaggerated pharmacodynamic effect.[316]

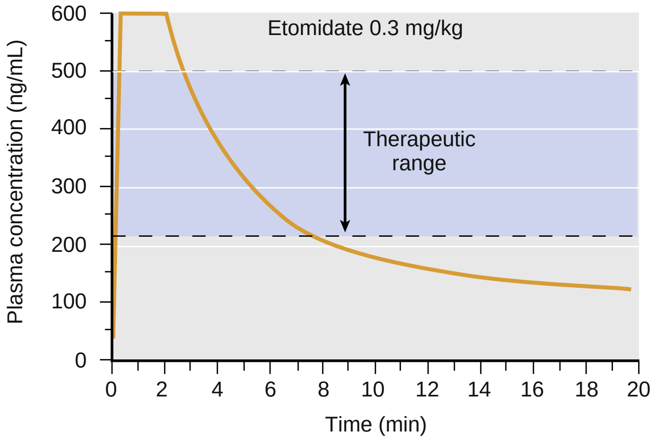

Fig. 23.17 Simulated time course of plasma levels of etomidate after an induction dose of 0.3 mg/kg. Plasma levels required for hypnosis during surgery are 300 to 500 ng/mL, with awakening usually occurring at levels less than 225 ng/mL.

Pharmacodynamics

EFFECTS ON THE CENTRAL NERVOUS SYSTEM

The primary action of etomidate on the CNS is through the $GABA_A$ receptor and results in hypnosis,[317,318] which is achieved in one arm–brain circulation after a normal induction dose (0.3 mg/kg). The mechanism by which etomidate produces hypnosis is almost exclusively through

$GABA_A$ receptor facilitation.[318,319] This includes two effects produced by different concentrations of etomidate. The first is the positive modulation of the $GABA_A$ receptor: activation of the receptor by agonists at concentrations associated with clinical doses. A lower dose of GABA is required in the presence of etomidate to activate the $GABA_A$ receptor.[320] The second action is called the direct activation or allosteric agonism. In supraclinical concentrations etomidate can directly, thus in absence of GABA, activate the $GABA_A$ receptor.[321] These two actions suggest two independent binding sites at the $GABA_A$ receptor.[318] These two binding sites on the $\alpha1\beta2\gamma2$ $GABA_A$ receptor contribute equally and non-cooperatively to drug interaction and gating effects. At a dose of 0.2 to 0.3 mg/kg, etomidate reduces CBF by 34% and $CMRO_2$ by 45% without altering MAP. CPP is maintained or increased, and there is a beneficial net increase in the cerebral oxygen supply-to-demand ratio.[322] Etomidate, given in doses sufficient to produce EEG burst suppression, acutely decreases ICP by 50% in patients with already increased ICP, returning increased ICP to almost normal values.[323] The decrease in ICP is maintained in the period immediately after intubation. To maintain the effects of etomidate on ICP, high infusion rates (60 μg/kg/min) are necessary. Controversy remains on the neuroprotective qualities of etomidate. There is a dose-dependent increase in latency and a decreasing amplitude of the auditory evoked potentials.[324]

Preliminary animal experiments suggest that in a case of acute fetal distress and hypoxic injury propofol and midazolam may be preferred over etomidate to protect the fetal brain as the first choice anesthetic in cesarean delivery.[199,325,326] Etomidate has been associated with grand mal seizures and produces increased EEG activity in epileptogenic foci. This feature has proven useful for intraoperative mapping of seizure foci before surgical ablation.[327,328] BIS monitor values decrease after etomidate bolus administration and return to baseline during recovery.[329] During etomidate infusion, the BIS values reliably predict the depth of sedation and hypnosis.[330]

Effects on the Respiratory System

Etomidate has less effect on ventilation than other anesthetics used to induce anesthesia. It does not induce histamine release in healthy patients or in patients with reactive airway disease.[331] Ventilatory response to carbon dioxide is depressed by etomidate, but the ventilatory drive at any given carbon dioxide tension is greater than that following an equipotent dose of methohexital.[153] Induction with etomidate produces a brief period of hyperventilation, sometimes followed by a similarly brief period of apnea,[332] which results in a slight (±15%) increase in $PaCO_2$, but no change in the partial pressure of arterial oxygen (PaO_2).[333] Etomidate's action on pulmonary vascular tone is similar to the actions observed with ketamine and propofol; that is, they attenuate the vasorelaxant responses to acetylcholine and bradykinine.[334]

Effects on the Cardiovascular System

The hemodynamic stability seen with etomidate is due to its lack of effect on the sympathetic nervous system and on the function of the baroreceptor. The effect of etomidate on the $\alpha2$-adrenoceptors generates an increase in blood pressure in vivo; this may contribute to the cardiovascular stability after induction of anesthesia. The minimal effect of etomidate on cardiovascular function sets it apart from other rapid-onset anesthetics.[335,336] Etomidate has proven useful in patients with valvular or ischemic heart disease undergoing noncardiac surgery and in patients with poor cardiac function.[337,338] In patients receiving etomidate during induction of anesthesia, more hypertension and tachycardia occurs after etomidate compared to propofol.[339] The myocardial oxygen supply-to-demand ratio is well maintained.[340] Etomidate lacks analgesic efficacy, however, and needs to be combined with an opiate to prevent hemodynamic perturbations during laryngoscopy and intubation.

In the setting of a hemorrhagic shock, etomidate provides advantages for induction of anesthesia. In contrast to other drugs, in a pig model of hemorrhagic shock the pharmacodynamics and pharmacokinetics of etomidate were minimally altered.[311]

Endocrine Effects

In 1983 Ledingham and Watt reported retrospective data showing increased mortality among intensive care patients receiving long-term etomidate infusion compared to patients receiving benzodiazepines.[304] They postulated that adrenal cortical suppression could be the cause of this increased mortality.

Soon after this publication, clinical investigators confirmed the adrenocortical suppression by etomidate.[305,341]

The specific endocrine effects manifested by etomidate are a dose-dependent reversible inhibition of the enzyme 11β-hydroxylase, which results in decreased biosynthesis of cortisol. The blockade of the cytochrome P450-dependent enzyme 11β-hydroxylase also results in decreased mineralocorticoid production and an increased formation of intermediaries (11-deoxycorticosterone) (Fig. 23.18). Subsequent research showed that etomidate is far more potent as an inhibitor of steroid synthesis than as a sedative hypnotic agent.[341,342] The etomidate concentrations associated with adrenal cortical suppression are less than 10 ng/mL, which are much lower than the concentrations needed for hypnosis (more than 200 ng/mL). The disparate concentrations for hypnosis and adrenotoxicity may explain the dramatic difference in duration of these two actions.[57]

The concerns about the use of etomidate and etomidate-induced adrenal toxicity in critically ill patients is still a matter of strong debate in the critical care community. A Cochrane review in 2015 of single-dose etomidate versus other induction agents for endotracheal intubation in critically ill patients reveals no conclusive evidence that etomidate increases mortality.[343] As indicated earlier, etomidate is associated with suppression of adrenal steroidogenesis, which can last up to 72 hours. However, the clinical impact of this adrenal suppressive effect is not certain.[344]

The Corticosteroid Therapy of Septic Shock (CORTICUS) study followed 500 patients with septic shock, who were randomized to receive either low-dose corticosteroid therapy or placebo. Twenty percent of the patients received etomidate. The study concluded that there was no benefit of low-dose corticosteroid therapy to long-term outcome.[345] Retrospective analyses of the CORTICUS population suggest that patients receiving etomidate before enrollment

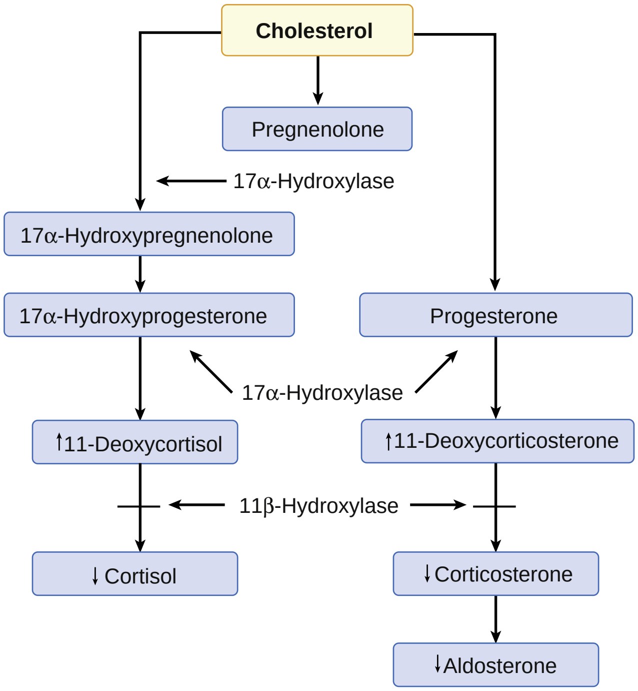

Fig. 23.18 Pathway for the biosynthesis of cortisol and aldosterone. The sites at which etomidate affects cortisol-aldosterone synthesis by its action on 11β-hydroxylase (major site) and 17α-hydroxylase (minor site) are illustrated.

had a 28-day mortality significantly higher and that steroid supplements provided no benefit.[346,347] Other studies designed to evaluate the effect of etomidate on morbidity and mortality and hospital and ICU length of stay are not conclusive.[348-351] In conclusion, the impact of the use of a single dose of etomidate in critically ill patients remains unclear.

Uses

INDUCTION OF ANESTHESIA

The induction dose of etomidate is 0.2 to 0.6 mg/kg.[352] The induction dose is reduced by premedication with an opiate, a benzodiazepine, or a barbiturate. Onset of anesthesia after a routine induction dose of 0.3 mg/kg of etomidate is rapid (one arm–brain circulation). Various infusion schemes have been devised to use etomidate as a maintenance anesthetic for the hypnotic component of anesthesia in the past. After the publications on the adrenocortical suppressive effects of etomidate, continuous infusion has been abandoned.

Etomidate is most appropriate in patients with cardiovascular disease, reactive airway disease, intracranial hypertension, or any combination of disorders indicating the need for an induction agent with limited or beneficial physiologic side effects. The hemodynamic stability of etomidate is unique among the rapid onset anesthetics used to induce anesthesia. In multiple studies, etomidate has been used for induction in patients with a compromised cardiovascular system who are undergoing coronary artery bypass surgery or valve surgery, and in patients requiring induction of general anesthesia for percutaneous transluminal coronary angioplasty, aortic aneurysm repair, and thoracic surgery. For cardioversion, the rapid onset, quick recovery, and maintenance of arterial blood pressure in these sometimes hemodynamically tenuous patients, combined with continued spontaneous respiration, make etomidate an acceptable choice.[353] Etomidate has been successfully used in neurosurgical procedures such as giant aneurysm clippings, making it a reasonable choice during neurosurgical induction.[354] In addition, etomidate should be considered as an anesthetic induction agent to reduce increased ICP when maintenance of cerebral or coronary perfusion pressure is also important.

Trauma patients with questionable intravascular volume status may be well served by an induction of anesthesia with etomidate. When using etomidate in trauma patients, loss of consciousness by itself can be associated with decreased adrenergic output, and controlled ventilation can exacerbate the cardiovascular effects of a decreased preload. Both of these factors may cause a significant decrease in arterial blood pressure during induction of anesthesia despite etomidate having no direct cardiovascular drug effect.

Short-term sedation with etomidate is useful in hemodynamically unstable patients, such as patients requiring cardioversion or patients requiring sedation after an acute myocardial infarction or with unstable angina for a minor operative procedure.[353] When used during electroconvulsive therapy, etomidate can produce longer seizures compared with other hypnotics.[355,356] Induction of anesthesia with etomidate is an independent risk factor in the development of an emergence delirium.[357]

Treatment in Hypercortisolemia

Etomidate has a special place in the treatment of endogenous hypercortisolemia. It is proven to be an effective parenteral treatment for this indication. In patients with unstable hemodynamics, patients with a sepsis, or patients with a psychosis, treatment should be performed under intensive care conditions.[358]

Side Effects

Although etomidate provides stable hemodynamics and minimal respiratory depression, it is associated with several adverse effects when used for induction, including PONV, pain on injection, myoclonic movement, and hiccups. More recently, etomidate in a lipid emulsion was associated with an equal or an increased incidence of postoperative nausea compared with propofol.[359-361]

The lipid formulation of etomidate is associated with a much less frequent incidence of pain on injection, thrombophlebitis, and histamine release.[362,363] Pain on injection may be reduced by injecting lidocaine, 20 to 40 mg immediately before injection of etomidate.

The incidence of muscle movement (myoclonus) and of hiccups is highly variable (0%-70%), but myoclonus is reduced by premedication with a hypnotic like midazolam or a small dose of magnesium 60 to 90 seconds before the induction dose of etomidate is given.[364,365]

Novel Etomidate Derivatives

Etomidate is a well-known and widely used anesthetic for induction of anesthesia. The limitations of etomidate are, as mentioned earlier, adrenocortical suppression, myoclonus, and PONV. Modifying etomidate could improve its clinical utility and produce etomidate derivatives with a better profile. Methoxycarbonyl etomidate (MOC) is an etomidate derivative and is rapidly metabolized to methoxycarbonyl etomidate carboxylic acid (MOC-ECA). MOC has almost equal hypnotic potency as etomidate, and the duration of the induced anesthesia is short due to rapid metabolization by nonspecific esterase enzymes. In preclinical studies MOC may not act as an inhibitor of adrenal steroid synthesis.[366] The accumulation of metabolites, leading to delayed recovery, makes it less than ideal for infusion.

Carboetomidate, another derivative, contains a five-membered pyrrole ring instead of an imidazole. In tadpoles and rats, carboetomidate reduces the adrenal suppression potency by three orders. Carboetomidate has potent hypnotic properties by activating $GABA_A$ receptors, which causes minimal hemodynamic changes.[367] Another potential benefit is its inhibition of the 5-HT3 receptor in a rat model; carboetomidate may have decreased emetogenic properties.

Another etomidate derivative, methoxycarbonyl-carboetomidate (MOC-carboetomidate), combines the favorable effects with no adrenal suppression and potency of the parent compound, but has a longer duration of action and makes it disadvantageous for longer infusions.

Cyclopropyl-methoxycarbonyl metomidate (CPMM) and dimethyl-methoxycarbonyl metomidate (DMMM) are the newest derivatives of etomidate. They have a higher potency and fast recovery time after infusion duration of 2 hours. So far, they are most promising in animal studies and inflammatory sepsis models.

Dexmedetomidine

HISTORY

The α_2-adrenergic receptor agonists have sedative, anxiolytic, hypnotic, analgesic, and sympatholytic effects. Its potential for use in anesthesia was recognized in patients who were treated with clonidine.[368] Soon a reduction of the minimum alveolar concentration (MAC) of halothane by clonidine was described.[369] Dexmedetomidine is a more selective α_2-agonist with a selectivity ratio for the α_2-receptor compared with the α_1-receptor of 1600:1, as compared to a ratio of 220:1 for clonidine. It was introduced in clinical practice in the United States in 1999 and approved by the FDA only as a short-term (<24 hours) sedative for mechanically ventilated adult ICU patients. Dexmedetomidine is used for prolonged sedation and anxiolysis in the ICU, as well as outside of the ICU in various settings, including sedation and adjunct analgesia in the operating room, sedation in diagnostic and procedure units, and for other applications such as withdrawal/detoxification amelioration in adult and pediatric patients.[370,371]

PHYSICOCHEMICAL CHARACTERISTICS

Dexmedetomidine is the S-enantiomer of medetomidine, a substance that has been used for sedation and analgesia in veterinary medicine for many years.[372] It shows a high ratio of specificity for the α_2-receptor ($\alpha_2/\alpha_1 = 1600{:}1$) compared with clonidine ($\alpha_2/\alpha_1 = 220{:}1$), making it a complete α_2-agonist.[373] The pK_a is 7.1. Dexmedetomidine belongs to the imidazole subclass of α_2-receptor agonists, similar to clonidine, and its structure is illustrated in Fig. 23.19. It is freely soluble in water and available as a clear isotonic solution containing 100 µg per mL and 9 mg sodium chloride per mL of water. Before infusion, this solution is diluted to a concentration of 4 µg/mL or 8 µg/mL by adding either saline, 5% glucose, mannitol, or Ringer lactate solution. It is not to be combined with amfoteracine B, amfoteracine B in liposomes, diazepam, phenytoin, gemtuzumab, irinotecan, or pantoprazole.

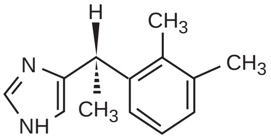

Fig. 23.19 Chemical structure of dexmedetomidine.

METABOLISM AND PHARMACOKINETICS

Dexmedetomidine undergoes almost complete biotransformation with very little unchanged dexmedetomidine excreted in urine and feces. Biotransformation involves both direct glucuronidation as well as cytochrome P450–mediated metabolism. The major metabolic pathways of dexmedetomidine are: direct N-glucuronidation to inactive metabolites, hydroxylation (mediated primarily by CYP2A6), and N-methylation. Polymorphism in CYP2A6 does not influence clinical dosing regimens.[374] Dexmedetomidine is 94% protein bound, and its concentration ratio between whole blood and plasma is 0.66. Dexmedetomidine has effects on cardiovascular variables, potentially causing bradycardia, transient hypertension or hypotension, and may alter its own pharmacokinetics. With large doses, there is marked vasoconstriction, which probably reduces the drug's volumes of distribution. The observed hypertension may be avoided by decreasing the loading dose or by increasing the time of administration.

In essence, dexmedetomidine displays nonlinear pharmacokinetics.[375] Its pharmacokinetics in volunteers are best described by a three-compartment model (see Table 23.1). Many subsequent studies in various patient populations have investigated the clinical pharmacokinetics and pharmacodynamics, the results of which are reviewed and summarized by Weerink and colleagues.[376] One of the findings is that the bodyweight adjustment dosing that is currently applied is only justified in a non-obese population. For obese patients, fat-free mass may be more appropriate, but this is still subject to investigation.

In subjects with varying degrees of hepatic impairment (Child-Pugh Class A, B, or C), clearance values for dexmedetomidine are slower than in healthy subjects. The mean clearance values for patients with mild, moderate, and severe hepatic impairment are 74%, 64%, and 53% of those observed in the normal healthy subjects, respectively.

The pharmacokinetics of dexemedetomidine are not influenced by renal impairment (creatinine clearance <30 mL/min) or age. In patients with severe renal disease, the sedative effect may be stronger, due to a lower

The top panel depicts the three α2 receptor subtypes acting as presynaptic inhibitory feedback receptors to control the release of norepinephrine and epinephrine from peripheral or central adult neurons. Also, a negative feedback loop has been seen in the adrenal gland. Alpha2B receptors have been involved in the development of the placental vascular system during prenatal development. The lower panel lists a series of physiologic effects with its associated α2 adrenoreceptors. (From Paris A, Tonner PH. Dexmedetomidine in anaesthesia. *Curr Opin Anaesthesiol*. 2005;18:412-418.)

degree of plasma protein binding. Clearance is a function of height.[375,377] The elimination half-life of dexmedetomidine is 2 to 3 hours, with a context-sensitive half-time ranging from 4 minutes after a 10-minute infusion to 250 minutes after an 8-hour infusion. Postoperative patients sedated with dexmedetomidine display similar pharmacokinetics to the pharmacokinetics seen in volunteers.[378] No clinically relevant cytochrome P450–mediated drug interaction has been found.

PHARMACOLOGY

Dexmedetomidine acts as a nonselective α_2-agonist on membrane bound G-protein coupled α_2-adrenoreceptors. Intracellular pathways include inhibition of adenylate cyclase and modulation of calcium and potassium ion channels. Three subtypes of α_2 adrenoreceptors have been described in humans: α_{2A}, α_{2B}, and α_{2C} (Fig. 23.20).[379] The α_{2A} adrenoreceptors are primarily distributed in the periphery, whereas α_{2B} and α_{2C} are in the brain and spinal cord. Postsynaptically located α_2 adrenoreceptors in peripheral blood vessels produce vasoconstriction, whereas presynaptic α_2 adrenoreceptors inhibit the release of norepinephrine, potentially attenuating the vasoconstriction. The overall response to α_2 adrenoreceptor agonists is related to the stimulation of α_2 adrenoreceptors located in the CNS and spinal cord. These receptors are involved in the sympatholysis, sedation, and antinociceptive effects of α_2 adrenoreceptors.[380] The α_2 agonists have the advantage that their effects are readily reversible by α_2-adrenergic antagonists (e.g., atipamezole).[381] Atipamezole is currently not approved for use in humans.

Effects on the Central Nervous System

SEDATION

The α_2 agonists produce their sedative-hypnotic effect by an action on α_2 receptors in the locus caeruleus and an analgesic action at α_2 receptors within the locus caeruleus and within the spinal cord.[382] Dexmedetomidine produces a decrease in activity of the projections of the locus caeruleus to the ventrolateral preoptic nucleus. As a result GABAergic and galanin release in the tuberomammillary nucleus is increased, producing a decrease in histamine release in cortical and subcortical projections.[383] The α_2 agonists inhibit ion conductance through L-type or P-type calcium channels and facilitate conductance through voltage-gated calcium-activated potassium channels. Dexmedetomidine induces sedation through different receptors than the sedative drugs propofol or benzodiazepines, which exert their action through the GABA system. The sedative effect of dexmedetomidine acts through the endogenous sleep-promoting pathways, generating natural sleep patterns (Fig. 23.21).[384] Patients have been described as being very easy to wake up and having the ability to follow commands and cooperate while being tracheally intubated. Undisturbed, patients were noted to fall asleep momentarily.[385] This characteristic allows for “daily wake up” tests to be done in a safe fashion. This critical test—when ventilated ICU patients are taken off all sedatives to assess their mental status and titrate sedation—shortens their ventilated and ICU length of stay.[386,387] The plasma concentration at which significant yet rousable sedation is achieved is about

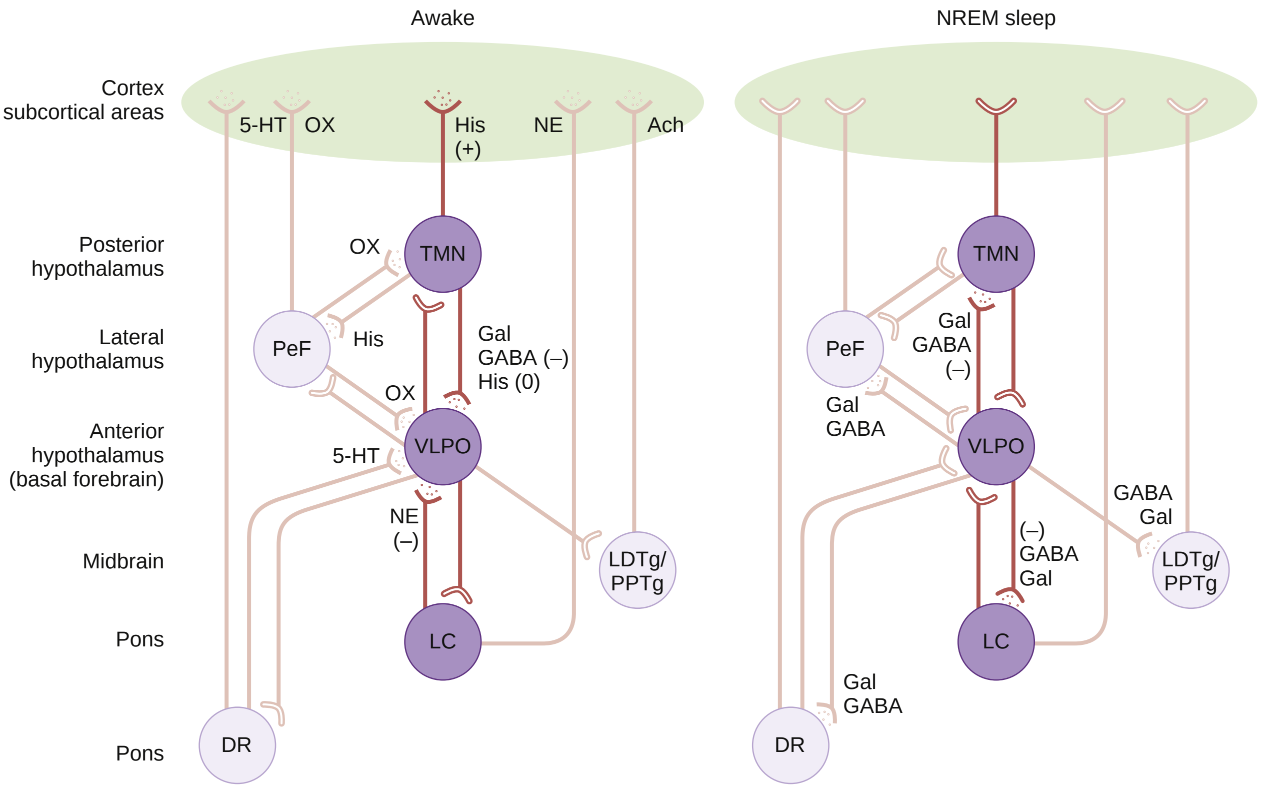

Fig. 23.21 Dexmedetomidine has been shown to induce a non–rapid eye movement sleeping pattern *(NREM)*. The stimulation of the locus caeruleus *(LC)* by dexmedetomidine (right diagram) releases the inhibition the LC has over the ventrolateral preoptic nucleus *(VLPO)*. The VLPO subsequently releases γ-aminobutyric acid *(GABA)* onto the tuberomammillary nucleus *(TMN)*. This inhibits the release of the arousal-promoting histamine on the cortex and forebrain, inducing the loss of consciousness. (From Ebert T, Maze M. Dexmedetomidine: another arrow for the clinician's quiver. *Anesthesiology*. 2004;101:569–570.)

0.2 to 0.3 ng/mL. Unarousable deep sedation is thought to occur at plasma concentrations above 1.9 ng/mL.[388]

The number of patients experiencing delirium in the ICU is significantly lower when sedated with dexmedetomidine, compared to propofol or lorazepam,[389] or midazolam.[390]

Although the precise mechanism by which dexmedetomidine preserves cognition is still unclear, there are data that suggest that the suppression of $\alpha 5$ γ-aminobutyric acid type A receptor expression after exposition to an anesthetic may play a role.[391]

ANALGESIA

The analgesic effect of the α_2 agonists is mediated through stimulation of the α_{2C} and α_{2A} receptor in the dorsal horn, directly suppressing pain transmission by reducing the release of pronociceptive transmitters, substance P and glutamate, and hyperpolarization of interneurons.[392] Systemic use of dexmedetomidine has an opioid sparing effect during surgery and postoperatively.[393] This is advantageous in patients who are prone to postoperative apnea or hypoventilation, as with patients undergoing bariatric surgery.[394] In the postoperative ICU setting, narcotic requirements are reduced by 50% when patients are receiving a dexmedetomidine drip compared with placebo.[385] During general anesthesia, it reduces the MAC of inhaled anesthetics.[395,396]

Like clonidine, dexmedetomidine is frequently used as an adjuvant in central or peripheral neural blockade. When administered caudally, 1 µg/kg as adjuvant to bupivacaine 0.25% 1 mL/kg, in children undergoing inguinal hernia repair, response to hernial sac traction is reduced and postoperative analgesia is prolonged.[397] Dexmedetomidine has been investigated in volunteers when administered as an adjuvant to ropivacaine in ulnar nerve block[398] and tibial nerve block.[399] Both studies showed intensification and foremost prolongation of the sensory blockade. This effect is likely elicited by prolonged hyperpolarization of the unmyelinated C-fibers (sensory), and to a lesser extent of the A-fibers (motor function).

Central Nervous System Protection and Other Central Nervous System Effects

The CNS protective effects are not well defined. Dexmedetomidine in animal models of incomplete cerebral ischemia and reperfusion reduces cerebral necrosis and improves neurologic outcome. The prevalent idea is that dexmedetomidine reduces the intracerebral catecholamine outflow during injury. The neuroprotection may be attributed to modulation of proapoptotic and antiapoptotic proteins.[400] Also, the reduction of the excitatory neurotransmitter glutamate during injury may explain some of the protective effects.[401]

In patients undergoing transsphenoidal hypophysectomy, dexmedetomidine has no effect on lumbar cerebral fluid pressure.[402] In other studies, CBF velocity at the middle cerebral artery, as measured by transcranial Doppler, decreased with increasing concentrations of dexmedetomidine but CO_2 responsiveness and autoregulation were preserved.[403,404] The decrease in CBF is not accompanied by a reduction in $CRMO_2$. More recently, in a study in six normal volunteers, the administration of dexmedetomidine to achieve serum levels of 0.6 ng/mL and 1.2 ng/mL (with and without hyperventilation) produced the predicted reduction of CBF with a concomitant reduction in $CRMO_2$.[405] This finding suggests that on the maintenance of the cerebral oxygen supply-to-demand relationship, further work in injured brains needs to be done.

Dexmedetomidine has been used in neurosurgical procedures involving neurophysiologic monitoring. Cortical evoked potentials, amplitudes, and latencies were minimally affected when using dexmedetomidine intraoperatively. It may also be suitable as an anesthetic adjunct during seizure surgery, since the epileptiform activity of seizure foci was not reduced by dexmedotomidine.[406]

EFFECTS ON THE RESPIRATORY SYSTEM

In spontaneous breathing volunteers, dexmedetomidine at concentrations producing significant sedation reduces minute ventilation, but results in no change in arterial oxygenation, pH, or the slope in the CO_2 ventilatory response curve. In a study comparing the effects of remifentanil and dexmedetomidine on respiratory parameters in normal volunteers, the hypercapnic ventilatory response was unaffected even at doses that produced unresponsiveness to vigorous stimulation.[407] Dexmedetomidine exhibited a hypercarbic arousal phenomenon, which has been described during normal sleep.

EFFECTS ON THE CARDIOVASCULAR SYSTEM

Ebert and colleagues performed a study in volunteers using a target-controlled infusion system to provide increasing concentrations (0.7 to 15 ng/mL) of dexmedetomidine (Fig. 23.22). The lowest two concentrations produced a decrease in MAP (13%) followed by progressive increase (12%). Increasing concentrations of dexmedetomidine also produce progressive decreases in heart rate (maximum 29%) and cardiac output (35%). The most commonly reported hemodynamic adverse reactions associated with dexmedetomidine in a phase III trial in 401 patients were hypotension (30%), hypertension (12%), and bradycardia (9%).[372] The initial increase in arterial blood pressure is probably due to the vasoconstrictive effects of dexmedetomidine

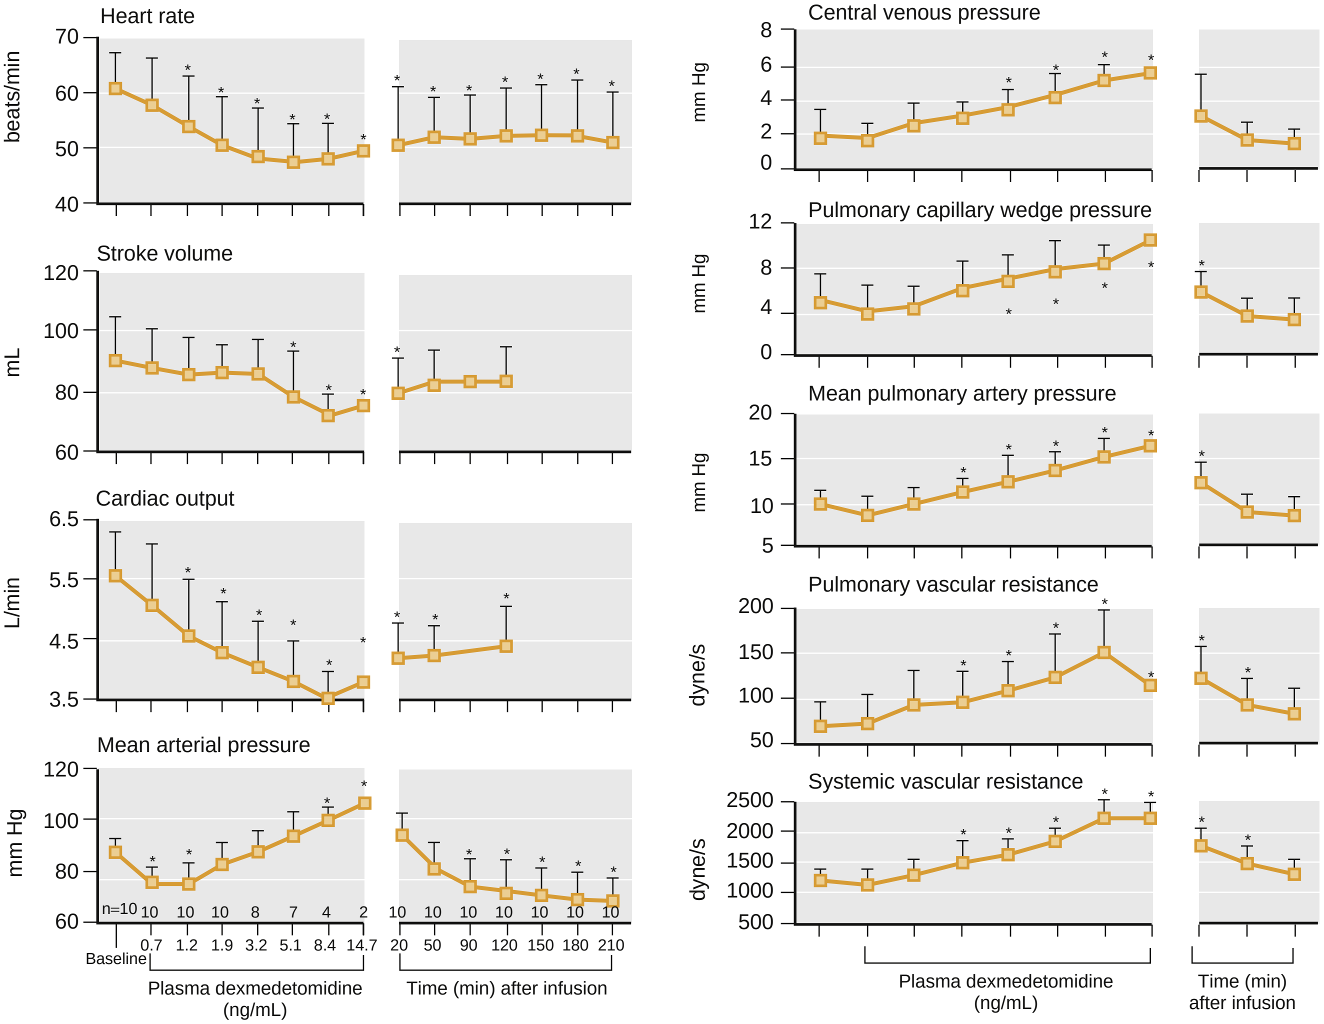

Fig. 23.22 Effects of increasing plasma concentrations of dexmedetomidine.

when stimulating peripheral α_2 receptors. The incidence of hypotension and bradycardia may be related to the administration of a large intravenous "loading" dose. Omitting the loading dose or not giving more than 0.4 µg/kg reduces the incidence of hypotension or makes it less pronounced. Giving the loading dose over 20 minutes also minimizes the transient hypertension.[408] In several studies after IM and IV administration, dexmedetomidine caused, in a small percentage of patients, profound bradycardia (<40 beats/min) and occasionally sinus arrest/pause. Generally, these episodes resolved spontaneously or were readily treated without adverse outcome by anticholinergics. No rebound effects have been found when discontinuing a dexmedetomidine infusion, even when it was given for more than 24 hours.[409] As clonidine and dexmedetomidine have shown to reduce perioperative oxygen consumption and blunt the sympathetic response to surgery, cardiac outcome may be improved.[410,411] However, more studies are needed to determine whether dexmedetomidine is beneficial in decreasing the risk of myocardial ischemia.

USES

Dexmedetomidine has been approved as a short-term sedative for adult intubated patients in the ICU. Given its well-documented beneficial effects of anxiolysis, sedation, analgesia, and sympatholysis with minimal respiratory depression, it also has been used in various other clinical scenarios. It is registered for use as a sedative during radiological or invasive procedures. Two studies, comprising 140 children 1 to 7 years old, reported successful sedation for MRI scans compared with midazolam or propofol.[412] For a thorough review of a wide range of studies on various procedures under sedation in different populations, we refer to Gerlach et al.[413]

As a premedicant, dexmedetomidine, at IV doses of 0.33 to 0.67 µg/kg given 15 minutes before surgery, seems efficacious, while minimizing the cardiovascular side effects of hypotension and bradycardia.[396] Dexmedetomidine has a high bioavailability when administered nasally or buccally. This improves compliance and absorption in younger children. A dose of 3 to 4 µg/kg 1 hour before surgery is safe and effective.

In a study comparing the efficacy of dexmedetomidine or propofol as a sedative agent in a group of 40 patients receiving local anesthesia or regional blocks, dexmedetomidine (1 µg/kg given over 10 minutes) when used for intraoperative sedation resulted in a slower onset than propofol (75 µg/kg/min for 10 minutes) but had similar cardiorespiratory effects when titrated to equal sedation. The average infusion rate of dexmedetomidine intraoperatively to maintain a BIS value of 70 to 80 was 0.7 µg/kg/min. Sedation was more prolonged after termination of the infusion, as was recovery of arterial blood pressure. Dexmedetomidine can also produce profound sedation, and it has been used as a total IV anesthetic when given at 10 times the normal sedation concentration range.[414] This characteristic, combined with the cooperative status of the patient at a lighter sedative level, and its analgesic effect with sparing of respiratory function, makes the drug suitable as a hypnotic during surgical procedures like awake craniotomy, deep brain stimulation, surgery near speech areas, or awake carotid endarterectomies, with fewer fluctuations from the desired sedation level and more stable hemodynamics.[403] A recent study shows that dexmedetomidine may be advantageous by improving the quality of emergence from general anaesthesia in avoiding coughing, agitation, hypertension, tachycardia, and shivering. This may be achieved by administration of dexmedetomidine 1 µg/kg intravenously at the end of surgery. Time to extubation is not prolonged.[415] The opioid-sparing effects are advantageous in the performance of bariatric surgery in patients who are prone to postoperative respiratory depression.[394]

Dexmedetomidine can be employed for addiction treatment; it has been described for use in rapid opioid detoxification, cocaine withdrawal, and iatrogenic-induced benzodiazepine and opioid tolerance after prolonged sedation.[416] The use in opioid/benzodiazepine withdrawal therapy in pediatric patients during mechanical ventilation in intensive care areas has been described as well.[417]

Dexmedetomidine may produce dry mouth due to a decrease in salivation. Combined with the sparing effect on respiratory function, this effect is beneficial for the facilitation of awake fiberoptic intubation, an application which is rapidly emerging.[418] Furthermore, dexmedetomidine decreases intraocular pressure and decreases the shivering threshold.[419]

The role of general anaesthesia in oncological surgery is still under debate. Studies of the in vitro and in vivo effects on lung carcinoma and neuroglioma cell lines have shown that dexmedetomidine enhanced cancer proliferation and migration, primarily by the upregulation of anti-apoptotic proteins. The clinical relevance of these findings remains to be determined.[163a]

INTENSIVE CARE UNIT

Dexmedetomidine may have advantages over propofol for sedation in mechanically ventilated postoperative patients. Heart rate was slower in the dexmedetomidine group, whereas MAP was similar. The PaO_2/FiO_2 ratio was significantly higher in the dexmedetomidine group. Time to extubation of the trachea after discontinuation of the infusion was similar at 28 minutes. Patients receiving dexmedetomidine had greater recall of their stay in the ICU, but all described this as pleasant overall.[421] Several other studies have confirmed the decreased requirement for opioids (>50%) when dexmedetomidine is used for sedation compared with propofol or benzodiazepines. Hemodynamics during weaning are more stable, which benefits patients with high risk for myocardial ischemia.[422] For sedation in the ICU, loading doses of 0.5 to 1 µg/kg have been used. Omitting the bolus dose or giving the lower dose has been associated with fewer episodes of severe bradycardia and other hemodynamic perturbations. Infusion rates of 0.1 to 1 µg/kg/h are generally needed to maintain adequate sedation. Delirium in the ICU is a risk factor for increased length of stay and increased mortality.[423] In a double-blind, randomized controlled trial of sedation in ventilated patients with dexmedetomidine versus lorazepam, it was found that using dexmedetomidine infusions provided more days alive without delirium or coma and a greater amount of time spent at the appropriate sedation level compared with lorazepam.[389] It also improved the patient's ability to communicate pain, compared to midazolam or propofol in two recent trials.[386] The unique characteristics of dexmedetomidine, that is providing adequate sedation with minimal respiratory depression, make this selective α_2-adrenoceptor agonist very useful when weaning patients from the ventilator.[424] While the FDA approved the use of dexmedetomidine infusions for 24 hours or less, multiple studies have shown the safety of using this agent for longer periods, even up to 30 days.[390]

Droperidol

HISTORY

Janssen[298,301] synthesized haloperidol, the first member of the butyrophenones, which became the primary neuroleptic component in neuroleptanesthesia. In 1959, DeCastro and Mundeleer combined haloperidol with phenoperidine (a meperidine derivative also synthesized by Janssen) in the forerunner to the practice of neuroleptanesthesia. Droperidol, a derivative of haloperidol, and fentanyl (a phenoperidine congener), both synthesized by Janssen, were used by DeCastro and Mundeleer in a combination they reported to be superior to haloperidol and phenoperidine. This neuroleptanesthesia combination produced more rapid onset of analgesia, less respiratory depression, and fewer extrapyramidal side effects. The fixed combination of droperidol and fentanyl, marketed as Innovar in the United States, was the drug primarily used for neuroleptanesthesia. The use of neuroleptanesthesia has largely disappeared in modern anesthetic practice. The primary use of droperidol in anesthesia has been as an antiemetic and to a lesser extent as a sedative and antipruritic. In addition, droperidol is used as an antipsychotic agent and to reduce agitation.[425]

In 2001, the FDA issued a black box warning regarding the use of droperidol and its potential for fatal arrhythmias and recommended that it be administered only during continuous electrocardiogram monitoring. With the withdrawal of droperidol in certain countries and more stringent labeling regarding potentially lethal dysrhythmias in others, the use of droperidol has decreased markedly. The validity of the risk of low-dose droperidol in causing QT prolongation, dysrhythmias, and death has been challenged by numerous editorials, articles, and letters reviewing the cases that prompted this action.[298,426-430] In Europe, 19 out of 25 countries with council members in the European Society of Anesthesiologists reported that droperidol is regularly used in a dosage of 0.5 to 2.5 mg for the prevention of PONV. Furthermore, in 2007, an international consensus panel recommended droperidol despite the FDA warning as a first-line antiemetic.[298,431]

Droperidol is a butyrophenone, a fluorinated derivative of phenothiazines (Fig. 23.23). Butyrophenones produce CNS depression, characterized by marked apparent tranquility and cataleptic immobility and are potent antiemetics. Droperidol is a potent butyrophenone, and, similar to the others, it produces its action centrally at sites where dopamine, norepinephrine, and serotonin act.[298,432] It has been postulated that butyrophenones may occupy GABA receptors on the postsynaptic membrane, reducing synaptic transmission and resulting in a build-up of dopamine in the synaptic cleft. In particular, droperidol results in a submaximal inhibition of the $GABA_A$ α_1, β_1, and γ_2 acetylcholine receptors and full inhibition of α_2 acetylcholine receptors. This submaximal inhibition of GABA receptors by droperidol may explain the anxiety, dysphoria, and restlessness that may occur with its administration.[298,433] An imbalance in dopamine and acetylcholine is thought to occur with subsequent alteration in normal transmission of signals in the CNS. The chemoreceptor trigger zone is the emetic center, and "red" astrocytes transport neurolept molecules from the capillary to dopaminergic synapses in the chemoreceptor trigger zone, where they occupy GABA receptors. This is thought to be the mechanism by which droperidol exerts its antiemetic effect.

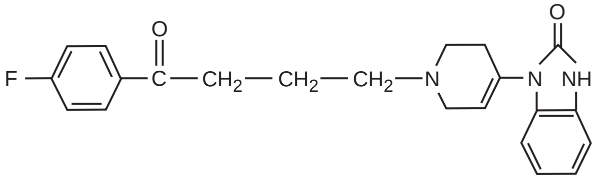

Fig. 23.23 Structure of droperidol, a butyrophenone derivative.

PHARMACOKINETICS

Droperidol is biotransformed in the liver into two primary metabolites. Its plasma decay can be described by a two-compartment model. The pharmacokinetics[298,434] is shown in Table 23.1.

Pharmacodynamics

EFFECTS ON THE CENTRAL NERVOUS SYSTEM

The effects of neurolept anesthetics on human CBF and $CMRO_2$ have not been studied. In dogs, droperidol causes potent cerebral vasoconstriction, producing a 40% reduction in CBF. No significant change in $CMRO_2$ occurs during droperidol administration. The EEG in conscious patients shows some reduction in frequency, with occasional slowing. Low-dose droperidol also has been shown to cause balance disturbances at the time of discharge after doses used for antiemetic prophylaxis. Droperidol may produce extrapyramidal signs and worsen symptoms of Parkinson disease, which is why the drug should be used with great caution in patients with this degenerative disorder. It also rarely may precipitate malignant neuroleptic syndrome.

EFFECTS ON THE RESPIRATORY SYSTEM

When used alone, droperidol has little effect on the respiratory system. Droperidol (0.044 mg/kg) given to surgical patients produced a slight reduction in respiratory rate, and IV droperidol (3 mg) had no significant effect on tidal volume in volunteers. More detailed respiratory studies are unavailable.

EFFECTS ON THE CARDIOVASCULAR SYSTEM

Similar to most antipsychotics, droperidol may prolong the QT interval by delaying myocardial repolarization and precipitating torsades de pointes.[298,435] This seems to be dose dependent and may be of clinical significance when other causes of QT prolongation also are present. Droperidol also may possess some antiarrhythmic effects that are similar to those of quinidine. Droperidol produces vasodilation with a decrease in blood pressure (see Table 23.3). This effect is considered to be a result of moderate α-adrenergic blockade. The dopamine-induced increase in renal blood flow (renal artery flowmeter methodology) is not significantly impaired by administration of droperidol. Droperidol has little effect on myocardial contractility.

USES

Use of droperidol today in the perioperative period is largely restricted to its antiemetic and sedative effects. It is an effective antiemetic; the dose for this use ranges from 10 to 20 μg/kg IV (typically 0.6-1.25 mg for a 70-kg individual).[298,436] Because droperidol in dosages below 1 mg produce antiemetic effects and because the cardiac side effects may be dose-dependent, an IV dose below 1 mg for prevention of PONV is advisable.[437] These doses of droperidol, given at the start of anesthesia for operations lasting 1 hour, reduce the incidence of nausea and vomiting by about 30%. These doses given at induction have little effect on wake-up time, but should they be given at the end of surgery, there could be some residual hypnotic effect. Overall, antiemetic efficacy of droperidol alone is equal to that of ondansetron and results in an equal number of side effects, but droperidol is more cost-effective. The efficacy of droperidol as an antiemetic is enhanced when used in combination with serotonin antagonists or dexamethasone, or both. Droperidol also has been shown to be effective in the treatment and prevention of pruritus secondary to opioid administration. It has been given intravenously and into the epidural space for this purpose. When used in this fashion, droperidol also effectively reduces nausea, but it increases sedation. The safety of droperidol administration into the epidural space has not been fully evaluated, however, and it is not approved for administration via this route.

Summary

Many different IV drugs are available for use in the care of patients requiring general anesthesia or sedation. The selection of a particular drug, but more often of a combination of drugs, must be based on the individual patient's need for hypnosis, amnesia, and analgesia. Drug selection must match the physiology and/or pathophysiology of the individual patient with the pharmacology of the particular drug(s). In addition, based on the pharmacokinetic and pharmacodynamic interactions now described, optimal dosage of hypnotic-analgesic combinations may be selected. A patient in shock who requires induction of anesthesia should receive the drug that produces rapid onset of effect without causing further hemodynamic compromise. The knowledge of the clinical pharmacology of each of the IV anesthetic drugs enables the clinician to induce and maintain sedation or general anesthesia safely and effectively. There is no single perfect drug for any particular patient, but rather the informed practitioner wisely employs the appropriate drug or drugs in the practice of good anesthesia care.

Acknowledgment

The editors and publisher would like to thank Drs. J.G. Reeves, Peter S.A. Glass, David A. Lubarsky, Matthew D. McEvoy, and Richardo Martinez-Ruiz for contributing a chapter on this topic in a previous edition of this work. It has served as the foundation for the current chapter.

24 Opioids

MARK SCHUMACHER and KAZUHIKO FUKUDA

KEY POINTS

- Opioids are a vital part of providing the analgesic component of anesthesia and often form the foundation for postoperative pain management.
- Opioids suppress pain by targeting multiple sites throughout the nervous system including action in brain, spinal cord, and peripheral nervous systems.
- An increased understanding of the molecular pharmacology of opioid receptors and opioid-induced cellular responses allows utilization of innovative techniques for analgesia.
- Opioids also affect multiple organ systems, including the respiratory and cardiovascular systems, and can cause a variety of adverse effects. Proper dosing and monitoring may allow these adverse effects to be minimized.
- Pharmacokinetic and pharmacodynamic properties of opioids are affected by a variety of factors, such as age, body weight, organ failure, shock, and drug interactions. To administer opioids, these factors should be taken into consideration.
- Although new opioid delivery systems such as transdermal patches provide certain clinical advantages, they can also pose additional risks such as respiratory depression.
- Opioid analgesics serve a critical role in acute pain management but their role in the long-term treatment of chronic noncancer pain has been called into question due to increased risks of overdose and addiction.

Introduction

The remarkable beneficial effects of opioids, as well as their toxic side effects and addictive potential, have been known for centuries. The term opioid refers broadly to all compounds related to opium. The word opium originates from *opos*, the Greek word for juice, the drug being derived from the juice of the opium poppy, *Papaver somniferum*. In contrast, the term opiate refers to natural products derived from the opium poppy and includes morphine, codeine, and thebaine.

The first undisputed reference to opium is found in the writings of Theophrastus in the third century B.C. During the Middle Ages, many of the uses of opium were appreciated. Opium contains more than 20 distinct alkaloids. In 1806, Sertürner reported the isolation of a pure substance in opium that he named morphine, after Morpheus, the Greek god of dreams. By the middle of the nineteenth century, the use of pure alkaloids rather than crude opium preparations began to spread throughout the medical world. Since then, there have been ongoing efforts to develop semisynthetic and synthetic opioid analgesics without the adverse side effects. Unfortunately, many of the synthetic opioids share side effects of natural opioids. The search for new opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist/antagonist properties, which further expanded therapeutic options and provided important tools for exploring mechanisms of opioid actions. Although new methods of opioid administration, including patient-controlled analgesia (PCA) and computer-based infusion techniques, have been developed, opioids continue to act on common binding sites throughout the nervous system.

Pharmacology of Opioids

CLASSIFICATION OF OPIOID COMPOUNDS

Opioids can be classified as naturally occurring, semisynthetic, and synthetic (Box 24.1). The naturally occurring opioids can be divided into two chemical classes, phenanthrenes (morphine and codeine) and benzylisoquinolines (papaverine). The semisynthetic opioids are morphine derivatives in which one of several changes has been made. Synthetic opioids are classified into four groups, the morphinan derivatives (levorphanol), the diphenyl or methadone derivatives (methadone, *d*-propoxyphene), the benzomorphans (phenazocine, pentazocine), and the phenylpiperidine derivatives (meperidine, fentanyl, sufentanil, alfentanil, and remifentanil). Structures of opioid compounds are shown in Fig. 24.1[1] and Table 24.1.[1]

Opioids can be classified as agonists, partial agonists, mixed agonist-antagonist, and antagonists on the basis of their interaction with the opioid receptors.

BASIC STUDIES ON OPIOID RECEPTORS

In 1973, three independent teams of investigators described the presence of opioid binding sites in the nervous system from the radioligand binding assays. From pharmacologic experiments, three types of opioid receptors were postulated. They were named μ for morphine type, κ for the ketocyclazocine type, and σ for the SKF10047 (*N*-allylnormetazocine) type. In addition, a high-affinity receptor for enkephalins was found in the mouse vas deferens, and was named the δ-receptor. Furthermore, an ε-receptor was

proposed as the binding site for β-endorphin in the rat vas deferens. Pharmacologic actions of opioids and the involved receptors have been analyzed (Table 24.2).

Since the early 1990s, molecular biologic studies have elucidated the molecular structures and signal transduction mechanisms of the opioid receptors. Four different complementary DNAs (cDNAs) have been isolated as members of the opioid receptor family.[2] Investigators demonstrated that three of them correspond to the pharmacologically defined μ-, δ-, and κ-opioid receptors. The fourth receptor did not bind with opioid ligands with high affinities. Later, a novel peptide, nociceptin/orphanin FQ, was identified as an endogenous agonist of the fourth member of the opioid receptor family.[3,4] The μ-, δ-, and κ-opioid receptors and the nociceptin receptor share approximately 50% amino acid sequence homology with each other. Characteristics of three opioid receptors and the nociceptin/orphanin FQ receptor are listed in Table 24.3. Hydropathy analysis of the primary structures of the opioid receptors predicted that the opioid receptors possess seven transmembrane domains (Fig. 24.2). This is a characteristic structural[5] feature of G-protein-coupled receptors. Crystallographic analysis revealed that the μ-, δ-, and κ-opioid receptors and the nociceptin receptor actually possess seven transmembrane domains and the agonist binds deeply within a large pocket (Fig. 24.3).[6] Furthermore, analysis of the crystal structure of the murine opioid receptor revealed agonist-induced conformational changes in detail, providing the basis for the development of new ligands.[7]

The σ (sigma) receptor, which was previously classified as a member of the opioid receptor, was shown to be an endoplasmic reticulum-resident protein, and has been implicated in many diseases, ranging from cocaine or alcohol addiction to the most recently reported familial adult or juvenile amyotrophic lateral sclerosis. The amino acid sequence of the σ-1 receptor does not resemble that of any other mammalian proteins.[8]

Further pharmacologic classification of the μ-receptor as the μ_1, μ_2, and μ_3 subtypes has been proposed, but the molecular identity of these receptor subtypes still remains to be clarified. Several possible molecular models of opioid receptor subtypes exist, including alternate splicing of a common gene product, receptor dimerization, and interaction of a common gene product with other receptor or signaling molecules.[9] Multiple μ-opioid receptor species can be produced from a gene product of the μ-opioid receptor gene by alternate splicing (Fig. 24.4).[10,11] Analysis of the alternate splicing products reveals differences in ligand binding and G-protein activation. However, their physiologic, pharmacologic, or clinical implications remain to be elucidated. Interestingly, it was recently reported that the analgesic action of 3-iodobenzoyl-6β-naltrexamide, a potent analgesic against thermal, inflammatory, and neuropathic pain, is mediated by its interaction with mMOR-1G, a truncated splice variant possessing only six transmembrane segments, in mice.[12]

G-protein-coupled receptors can form dimers, homodimers (same receptor), and heterodimers (different receptor types). The existence of these homodimers and heterodimers has been shown in cultured cells and *in vivo.* Among opioid receptors (μ, δ, κ, and nociception receptors), various combinations of the molecules have been shown to form dimers, and the dimer formation has been shown to affect the ligand binding properties and signal transduction mechanisms.[13] Physiologic and clinical implications of dimer formation of opioid receptors will be further clarified. For example, it is interesting that a bivalent ligand containing μ-agonist and δ-antagonist pharmacophores effectively bridges μ-δ opioid receptor heterodimers and exhibits enhanced efficacy and a reduced tendency for tolerance in mice.[14] However, in the peripheral nervous system, μ and δ receptors are apparently expressed in different sensory neuronal subpopulations.[15,16]

Taken together, the overwhelming evidence of opioid receptor diversity in structure, ligand binding, and distribution supports the concept they serve both essential and complex signaling roles throughout the nervous system.

GENETIC VARIATIONS WHICH INFLUENCE OPIOID EFFECTS

Several single nucleotide polymorphisms (SNPs) have been identified in the human μ-opioid receptor gene (Fig. 24.5).[17] The A118G mutation, the most common of these SNPs, leads to a change in the gene product in the human μ-opioid receptors, which is an A-to-G substitution in exon 1 that results in an amino acid exchange at position 40 from asparagine to aspartate (N40D). Patients with cancer who are homozygous for the A118G variant required higher doses of oral morphine for long-term treatment of their pain.[18] A118G mutation of the human μ-opioid receptor gene reduces analgesic responses to morphine-6-glucuronide (M6G), but it does not significantly affect the respiratory depression induced by M6G.[19] Furthermore, morphine consumption with intravenous PCA after total abdominal hysterectomy is significantly greater in women homozygous for the A118G variant than in other patients.[20] In a meta-analysis involving 18 studies and more than 4600 patients, carriers of A118G were observed to exhibit higher opioid analgesic requirements.[21] Another meta-analysis showed significant association between A118G polymorphism and susceptibility to opioid dependence or addiction in Asian populations.[22]

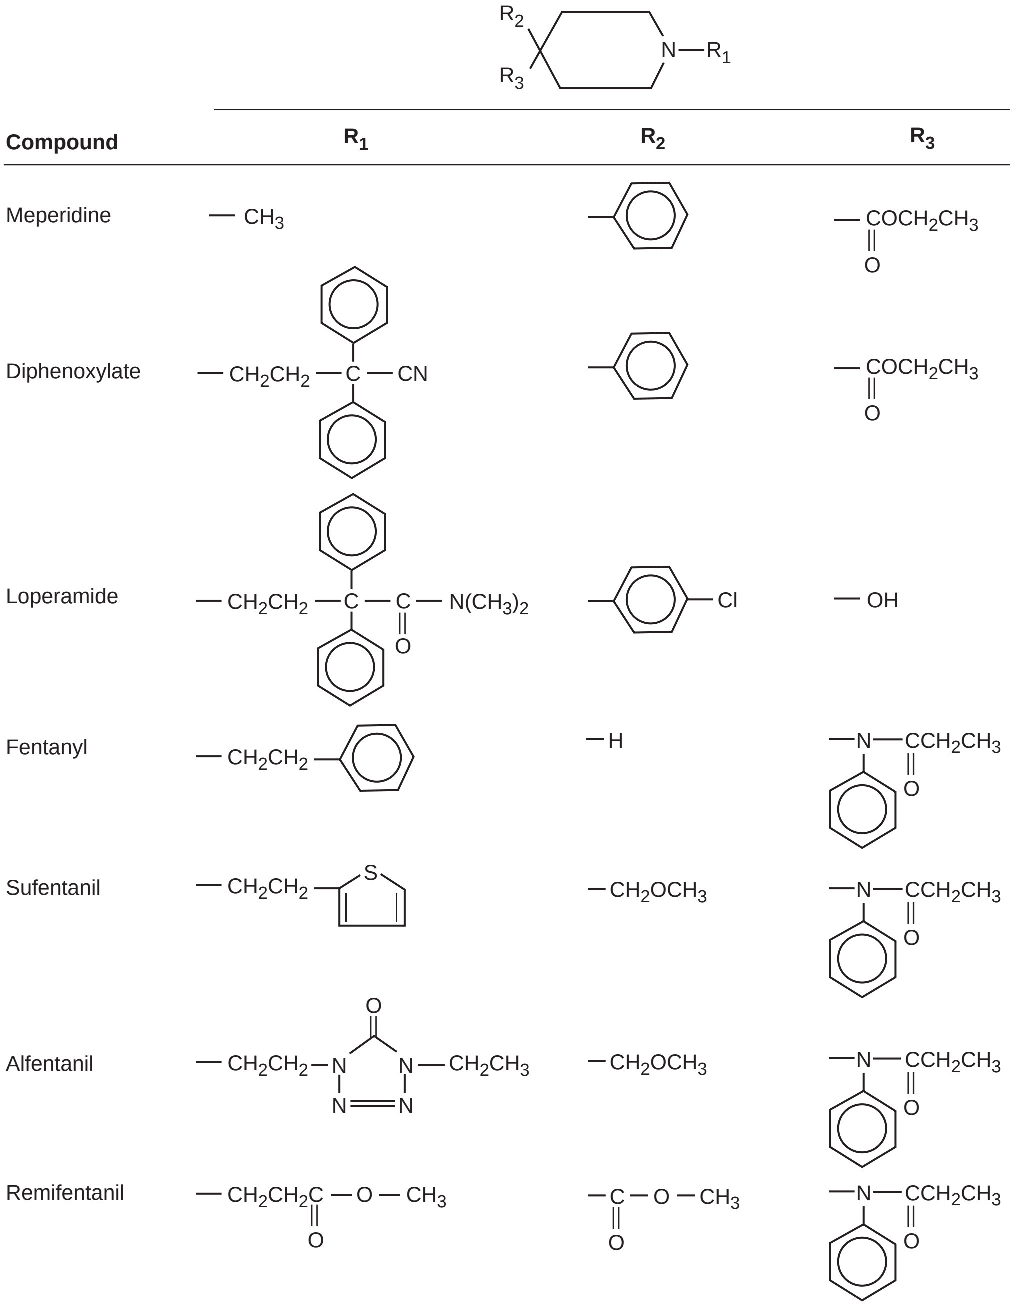

Fig. 24.1 **Chemical structures of piperidine and phenylpiperidine analgesics.** (From Gutstein HB, Akil H. Opioid analgesics. In: Hardman JG, Limbird LE, eds. *Goodman and Gilman's the Pharmacological Basis of Therapeutics*. 10th ed. New York: McGraw-Hill; 2001:569–619.)

In vitro experiments show that the variant receptors with A118G mutation are associated with higher binding affinity to and potency of β-endorphin, but lower potency of morphine.[23] Studies in mouse models with analogous substitution of human A118G showed reduced analgesic response to morphine in some regions of the mouse brain with the GG genotype when compared with the AA genotype.[24] A study also showed that 118A messenger RNA was 1.5- to 2.5-fold more abundant than the 118G messenger RNA in heterozygous brain autopsy tissues.[25]

Overall, these findings suggest that the 118G allele may result in changes in abundance and/or function of the μ-opioid receptor leading to differences in antinociceptive potency of opioid analgesics. This in turn could misdirect healthcare providers in providing the most effective and safe opioid-based analgesic plan.

The C17T mutation of the human μ-opioid receptor, located in exon 1, causes an amino acid exchange from alanine to valine at receptor protein position 6 of the extracellular receptor terminal. This mutation has been reported to occur in a higher overall proportion of opioid-dependent persons, but the effects of the C17T polymorphism on analgesic responses are unknown. A recent study using cultured cells reported that adenylate inhibition via the C17T polymorphism was decreased for many opioids, including the clinically significant drugs morphine, buprenorphine,

and fentanyl, as well as endogenous opioids,[26] suggesting that this polymorphism may affect individual responses to opioid therapy, while the possible disruption of the endogenous opioid system may contribute to susceptibility to substance abuse.

It is known that genetic variation of genes other than opioid receptor genes can affect sensitivity to opioids. It has been demonstrated that the Val158Met polymorphism of the human catechol-*O*-methyltransferase (COMT) gene has contributed to differences in opioid consumption in patients treated for chronic cancer pain,[27] and is associated with variability in opioid consumption in postoperative nephrectomy patients.[28] COMT metabolizes biogenic amines including catecholamines such as dopamine, epinephrine, and norepinephrine, thereby acting as a key modulator of dopaminergic and adrenergic neurotransmission, and can affect the pharmacologic effects of opioids. Some studies have explored the relationship between gene-gene interactions and opioid responses. Kolesnikov and associates have demonstrated that the heterozygous patients with μ-opioid receptor A118G and COMT G1974A mutation consumed significantly less morphine compared with homozygous patients of A118.[29] As investigation into the clinical impact of genetic variability continues, it is revealing that even greater complexity exists between gene-gene interactions and postoperative morphine consumption.[30]

ENDOGENOUS OPIOID PEPTIDES

Enkephalin, β-endorphin, and dynorphin were identified as endogenous agonists for the δ-, μ-, and κ-opioid receptors, respectively. Following purification of these peptides from mammalian tissues, cDNAs for the precursors of these peptides were cloned. cDNA cloning and amino acid determination of preproopiomelanocortin demonstrated that the cleavage of this precursor protein produces not only β-endorphin but also several other neuropeptides including methionine-enkephalin, adrenocorticotropic hormone (ACTH), and α-melanocyte stimulating hormone. Amino acid sequence of preproenkephalin indicates that four methionine enkephalins and one leucine-enkephalin are cleaved from this precursor. Furthermore, the primary structure of preprodynorphin, the precursor of dynorphin, gives rise to dynorphin, leumorphin, and neoendorphin—ligands for the κ-opioid receptor.

Orphanin FQ or nociceptin, a novel endogenous opioid peptide with a significant sequence homology to dynorphin, was isolated in 1995[3,4] and so named because it lowered pain threshold under certain conditions in contrast to other endogenous opioid peptides. Pharmacologic and physiologic studies have demonstrated that orphanin FQ/nociceptin has behavioral and pain modulatory properties distinct from those of the three classic opioid peptides.[31] However, studies of the effect of orphanin FQ/nociceptin on pain sensitivity have produced conflicting results, which may suggest that the effects of orphanin FQ/nociceptin on pain sensitivity depend on the underlying behavioral state of the animal. Prepronociceptin, the precursor of orphanin FQ/nociceptin, was cloned, and its amino acid sequence suggested the existence of prepronociceptin-derived neuropeptides other than orphanin FQ/nociception.[32]

The search for endogenous ligand binding with the μ receptor with high affinity and high selectivity led to the discovery of a class of novel endogenous opioids termed endomorphin-1 and endomorphin-2.[33] These peptides are tetrapeptides with the sequence Tyr-Pro-Trp-Phe and Tyr-Pro-Phe-Phe, respectively. An endomorphin gene has yet to be cloned, and much remains to be learned about the anatomic distribution, mode of interaction with the opioid receptors, function in vivo, and potential existence of other related peptides that are highly selective for each of the opioid receptors. It was recently demonstrated that both endomorphin-1 and endomorphin-2 given centrally and peripherally produced potent antiallodynic activities in a mouse model of neuropathic pain,[34] and downregulation of endomorphin-2 correlates with mechanical allodynia in a rat bone cancer pain model.[35]

INTRACELLULAR SIGNAL TRANSDUCTION MECHANISM OF OPIOID RECEPTORS

The opioid receptors belong to the G-protein-coupled receptor family. It has been demonstrated that activation of the opioid receptors leads to activation of the pertussis toxin-sensitive G proteins (G_i or G_o or both). Expression of the cloned opioid receptors in cultured cells by transfection of the cloned cDNAs has facilitated analysis of the intracellular signal transduction mechanisms activated by the opioid receptors (Fig. 24.6).[2] Adenylate cyclase is inhibited by opioid receptor activation, with a resulting reduction of the cellular cyclic adenosine monophosphate (AMP) content. Electrophysiologically, the voltage-gated Ca^{2+}

channel is inhibited and the inwardly rectifying potassium (K^+) channels are activated by the opioid receptors. As a result, neuronal excitability is reduced by activation of the opioid receptors. However, the role of adenylate cyclase in opioid receptor activation is complex. For example, long-term tolerance to opioids has been thought to be associated with superactivation of adenylyl cyclase activity, which is a counterregulatory response to the decrease in cyclic AMP levels seen after acute opioid administration.[36] That this effect is prevented by pretreatment of cells with pertussis toxin demonstrates involvement of G proteins (G_i or G_o or both).

Beyond adenylate cyclase, other regulatory components participate in the coupling of opioid receptor binding and a cellular response. It was shown that extracellular signal-related kinase, a class of mitogen-activated protein kinases, is activated by the opioid receptors.[37] Opioid-induced activation of extracellular signal-related kinase can lead to increase in arachidonate release[37] and expression of immediate early genes, c-fos and junB.[38]

Chronic exposure of the opioid receptors to agonists induces cellular adaptation mechanisms, which may be involved in opioid tolerance, dependence, and withdrawal symptoms. Several investigators have shown that short-term desensitization probably involves phosphorylation of the opioid receptors through protein kinase C.[39] A number of other kinases also have been implicated, including protein kinase A and β-adrenergic receptor kinase (BARK), a member of the G-protein-coupled receptor kinase (GRK).[40] BARKs selectively phosphorylate agonist-bound receptors and thereby promote interactions with β-arrestins, which interfere with G-protein coupling and promote receptor internalization. β-Arrestin 2 functions as a scaffolding protein that interacts with signal transducers, and the recruitment of β-arrestin 2 induced by opioid receptor activation is involved in the regulation of activity of c-Src, Akt, and mitogen-activated protein kinases (Fig. 24.7).[41] The c-Src inhibitor, dasatinib, attenuated and reversed morphine-induced tolerance in mice, suggesting that c-Src recruited by β-arrestin 2 is involved in the morphine-induced tolerance.[42] Acute morphine-induced analgesia was enhanced in mice lacking β-arrestin 2, suggesting that this protein contributes to regulation of responsivity to opioids *in vivo*.[43] Therefore, β-arrestin modification by associated kinases serves a critical role in the coupling between agonist binding to opioid receptors and their ability to develop and sustain an analgesic response.

Like other G-protein-coupled receptors, the opioid receptors can undergo rapid agonist-mediated internalization by a classic endocytic pathway.[44,45] These processes may be induced differentially as a function of the class of the ligand. For example, certain agonists, such as etorphine and enkephalins, cause rapid internalization of the μ receptor, whereas morphine, which decreases adenylyl cyclase activity equally well, does not cause μ receptor internalization in all cell types such as HEK293 cells.[46] Although these findings may suggest that different ligands induce different conformational changes in the receptor that lead to divergent intracellular events, they also have revealed that rapid morphine–dependent μ receptor endocytosis is still possible in subpopulations of central nervous system (CNS) neurons such as striatal neurons.[47] Taken together, they may help provide an explanation for differences in the efficacy and abuse potential of various opioids.[48]

BIASED AGONISM

Chemically distinct ligands binding to the same G-protein–coupled receptor can stabilize the receptor in multiple active conformations. In this way, differential activation of G-protein–coupled cell signaling pathways may produce divergent physiologic outcomes, a phenomenon known as biased agonism. Biased agonism can be exploited to design drugs that selectively activate desired signaling pathways, while minimizing other signaling pathways via the same receptor subtype and associated side effects.

Morphine binds to the μ-opioid receptor protein to form an active complex with signaling proteins, including $G_{i/o}$ and β-arrestin. The $G_{i/o}$ signaling pathway is thought to mediate analgesic action of morphine, whereas β-arrestin signaling results in unwanted side effects including euphoria, which can lead to addiction, respiratory depression, and gastrointestinal effects. Consistently, it was shown that the analgesic properties of morphine were enhanced but morphine-induced respiratory depression and constipation were attenuated in β-arrestin 2 knockout mice.[49] Emerging research in this evolving field includes a report by Manglik and associates, who computationally screened 3 million molecules, resulting in the compound PZM21, which showed high $G_{i/o}$-biased signaling and suppressed pain in mice without constipation, respiratory depression, hyperlocomotion, and addiction–related behaviors.[50] The clinical importance of these findings awaits further confirmation given other reports showing little difference in adverse effect profiles between morphine and PZM21 in

mice.[51] However, TRV130, a "G protein-biased" μ-opioid ligand with G-protein–coupling efficacy similar to that of morphine, but markedly reduced receptor phosphorylation, recruitment of β-arrestin 2, and internalization, was tested in a randomized, double-blind, placebo-controlled crossover study in healthy volunteers.[52] TRV130 produced greater analgesia than morphine, but less respiratory depression and less severe nausea (Fig. 24.8). As additional biased-agonist candidates of the μ-opioid receptor emerge, so does the hope for a new generation of clinically effective analgesics with a reduced profile of harm.

MECHANISM OF OPIOID ANALGESIA

Brain

Pain control by opioids needs to be considered in the context of brain circuits modulating analgesia and the functions of the various types of receptors in these circuits.[53] It is well established that the analgesic effects of opioids arise from their ability to inhibit directly the ascending transmission of nociceptive information from the spinal cord dorsal horn and to activate pain control circuits that descend from the midbrain, through the rostral ventromedial medulla (RVM), to the spinal cord dorsal horn. Petrovic and colleagues used an experimental pain model and positron emission tomography (PET) to study mechanisms of action of the short-acting μ-opioid agonist remifentanil and found drug-induced activation of the rostral anterior cingulate cortex, insula, orbitofrontal cortex, and brainstem areas.[54]

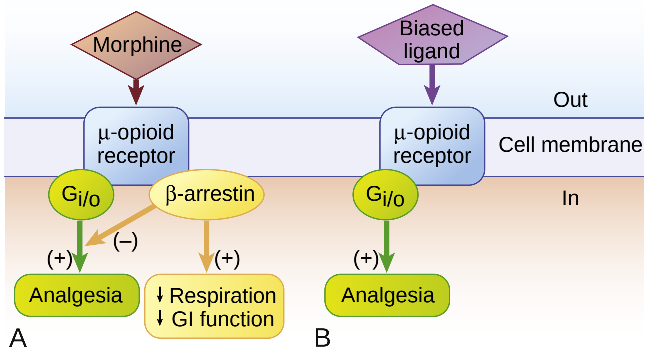

Fig. 24.8 Biased agonism. (A) Morphine binding to the μ-opioid receptor not only activates the G protein ($G_{i/o}$) analgesic effect, but also recruits β-arrestins, which inhibits G protein coupling and promotes hypoventilation and gastrointestinal dysfunction. (B) *TRV130*, a G protein–biased agonist, engages G-protein coupling similarly to morphine but with less β-arrestin recruitment, resulting in analgesic effect similar to morphine and less effects on respiratory and gastrointestinal function.

The activated brainstem regions overlapped with brain areas that have been implicated in pain modulation, such as the periaqueductal gray (PAG). Interestingly, placebo analgesia acts similarly on the activity of these brain areas, presumably via endogenous opioid release.[55]

Immunohistochemical studies and in situ hybridization analysis have demonstrated that opioid receptors are expressed in various areas in the CNS.[56] These areas include the amygdala, the mesencephalic reticular formation, the PAG, and the RVM. However, the role of the opioid receptors in all of these areas has not been completely clarified.

Microinjection of morphine into the PAG or direct electrical stimulation of this area produces analgesia that can be blocked by naloxone. Opioid actions at the PAG influence RVM, which in turn modulates nociceptive transmission in the dorsal horn of the spinal cord through the action of the descending inhibition pathway. Thus, opioids produce analgesia by direct actions on the spinal cord, as well as by neurally mediated action in the region separated from the site of opioid administration. Interestingly, a study by Dogrul and Seyrek reported that spinal serotonin 5-HT7 receptors play an important role on the antinociceptive effects of systemic morphine.[57]

It is well known that the actions of opioids in bulbospinal pathways are critical to their analgesic efficacy. It is clear that opioid actions in the forebrain contribute to analgesia, because decerebration prevents analgesia when rats are tested for pain sensitivity using the formalin test,[58] and microinjection of opioids into several forebrain regions are analgesic in this test.[59] Analgesia induced by systemic administration of morphine in both the tail-flick and formalin tests was disrupted either by lesioning or reversibly inactivating the central nucleus of the amygdala, thereby demonstrating that opioid actions in the forebrain contribute to analgesia after tissue damage, as well as after acute phasic nociception.[60]

The distribution of opioid receptors in descending pain control circuits indicates substantial overlap between μ and κ receptors. Interactions between the κ receptor and the μ receptor may be important for modulating nociceptive transmission from higher nociceptive centers, as well as in the spinal cord dorsal horn. The μ receptor produces analgesia within descending pain control circuits, at least in part, by the removal of γ-aminobutyric acidergic inhibition of RVM-projecting neurons in the PAG and spinally projecting neurons in the RVM.[53] The actions of μ-receptor agonists are invariably analgesic, whereas those of κ-receptor agonists can be either analgesic or antianalgesic. The pain-modulating effects of the κ-receptor agonists in the brainstem appear to oppose those of μ-receptor agonists.[61]

Spinal Cord

Analgesic actions of systemic morphine are in part mediated by a net inhibitory effect from the PAG and RVM on nociceptive processing in the spinal dorsal horn. It was demonstrated that morphine increased 5-HT release in the spinal dorsal horn by activation of serotonergic neurons in the RVM, and intrathecal pretreatment with ondansetron attenuated the analgesic effect of morphine in normal rats, suggesting the involvement of the 5-HT$_3$ serotonergic receptor in morphine analgesia.[62]

Local spinal mechanisms, in addition to descending inhibition, underlie the analgesic action of opioids. In the spinal cord, opioids act at synapses either presynaptically or postsynaptically. Opioid receptors are abundantly expressed in the substantia gelatinosa, where glutamate and substance P release from the primary sensory neuron is inhibited by opioids. Histamine receptors are known to participate in spinal cord nociceptive transmission, and previous studies have suggested that histaminergic receptors are also involved in the analgesic effects of morphine. An H$_1$ antagonist and H$_3$ agonist were found to potentiate the analgesic and antiedematogenic effects of morphine, suggesting that histaminergic and opioid spinal systems may be explored for means of improving analgesia, as well as peripheral antiinflammatory effects.[63]

Opioid-receptor ligand binding has been identified in both presynaptic and postsynaptic sites in the dorsal horn of the spinal cord. It is well known that opioids decrease the pain-evoked release of tachykinins from primary afferent nociceptors. However, the degree that opioids can suppress tachykinin signaling in response to noxious stimulation remains controversial.[64] These results suggest that although opioid administration may reduce tachykinin release from primary afferent nociceptors, the reduction may not be a major modulator on the actions of tachykinins on postsynaptic pain-transmitting neurons.

Peripheral Mechanism

Opioids may also produce analgesia through the peripheral mechanism.[65] Immune cells infiltrating the inflammation site may release endogenous opioid-like substances, which act on the opioid receptors located on the primary sensory neuron.[65] Interestingly, in cannabinoid receptor type 1 and type 2 knockout mice, the antinociceptive effect of morphine injected into the paw in the inflammatory phase of the formalin test was decreased by 87% and 76%, respectively.[66] This finding may suggest the possibility that the release of endogenous cannabinoids in structures along the pain pathway is involved in opioid analgesia by the peripheral mechanism.

Acupuncture

Acupuncture and electroacupuncture have been shown to block pain by activating a variety of bioactive chemicals through peripheral, spinal, and supraspinal mechanisms. Mechanistically, endogenous opioids and opioid receptors have been shown to be involved in acupuncture- and electroacupuncture-induced analgesia in various pain models.[67] Studies in carrageenan-induced inflammatory rat pain models show that an intraplantar injection of naloxone or selective antagonists against μ-, δ-, or κ-opioid receptors 1 hour before electroacupuncture treatment at acupoint *Zusanli* (ST36) dose-dependently blocked electroacupuncture-produced inhibition of mechanical hyperalgesia assessed through paw-pressure threshold.[68] In a capsaicin-induced inflammatory hind paw pain model, stimulation by 2 Hz of four-train pulses with 100 Hz of intratrain frequency at *Houxi* (SI3) and *San-yangluo* (TE8) on the forelimb significantly raised the mechanical pain threshold of the injected paw. This analgesic effect was blocked by intrathecal μ- or δ-opioid receptor antagonists but not by a κ-opioid receptor antagonist.[69] Precise mechanisms for acupuncture and electroacupuncture, including the involvement of physiologic systems other than the opioid receptors, remain to be elucidated.

MECHANISM OF MOOD ALTERATIONS AND REWARDING PROPERTIES

The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) remain an area of active investigation, especially given the expanding scope of opioid diversion and misuse. Behavioral and pharmacologic evidence points to the role of dopaminergic pathways, particularly involving the nucleus accumbens (NAcc), in drug-induced reward. Functional magnetic resonance imaging studies demonstrated that a small intravenous dose (4 mg) of morphine induces positive signal changes in reward structures, including the NAcc, sublenticular extended amygdala, orbitofrontal cortex, and hippocampus, and decreases signal in cortical areas similar to the action of sedative-hypnotics such as propofol and midazolam.[70] These observations are consistent with results of pharmacologic studies.

The shell of the NAcc is the site that may be involved directly in the emotional and motivational aspects of drug-induced reward. All three opioid receptor types are present on the NAcc and are thought to mediate, at least in part, the motivational effects of opioid drugs.[56] Selective μ- and δ-receptor agonists are rewarding when defined by place preference and intracranial self-administration paradigms. Conversely, selective κ-receptor agonists produce aversive effects. Positive motivational effects of opioids are partially mediated by dopamine release at the level of the NAcc.

The locus ceruleus contains both noradrenergic neurons and high concentrations of opioid receptors and is postulated to play a critical role in feelings of alarm, panic, fear, and anxiety. Neural activity in the locus ceruleus is inhibited by both exogenous opioids and endogenous opioid peptides.

ANALYSIS OF KNOCKOUT MICE

The physiologic roles of the opioid receptors and endogenous opioid peptides have been investigated mainly by pharmacologic and physiologic methods. However, it has been difficult to analyze functional roles of these proteins. With analysis of knockout mice, in which a specific gene is inactivated by molecular biologic methods, additional insight into the physiologic role of the respective opioid receptors and/or endogenous opioid peptide precursors can be determined.[71]

In the μ-receptor knockout mice, analgesia, the reward effect, and the withdrawal effect of morphine were lost.[72] Morphine-induced respiratory depression was not observed in the μ-receptor knockout mice.[73] Therefore, the μ-receptor is a mandatory component of the opioid system for morphine action. In the μ-receptor knockout mice, ketamine-induced respiratory depression and antinociception are diminished,[74] a finding suggesting that ketamine interacts with the μ receptor to lead to these phenomena. Furthermore, minimum alveolar concentration (MAC) of sevoflurane was significantly higher in the μ-receptor knockout mice than wild-type mice, an observation suggesting the involvement of the μ receptor in the anesthetic potency of sevoflurane.[73] The δ-receptor knockout mice displayed a markedly reduced analgesic effect of opioids selective for δ-receptors at the spinal cord level.[75] However, at the supraspinal level, analgesia could be induced by δ-receptor agonists in δ-receptor knockout mice, a finding suggesting the existence of a second δ-like analgesic system. Disruption of the κ receptor abolished the analgesic, hypolocomotor, and aversive actions of the κ-receptor agonists and induced hyperreactivity in the abdominal constriction test; this finding indicates that the κ receptor is involved in the perception of visceral chemical pain.[76] Using gene knockout mice, a pharmacologic study demonstrated that the antinociceptive effect of N_2O may not be mediated by μ-receptor[77]; rather N_2O exerts its antinociceptive action and reduces MAC of volatile anesthetics in mice through complex mechanisms including activation of the κ receptor and the descending inhibitory pathway in the spinal cord, whereas its hypnotic potency is not dependent on κ-receptor activation.[78]

In the mice lacking β-endorphin, morphine induced normal analgesia, but naloxone-reversible stress-induced analgesia could not be observed.[79] The preproenkephalin knockout mice were more anxious than wild-type mice, and males displayed increased offensive aggressiveness.[80] The mutant mice showed marked difference from controls in supraspinal, but not in spinal, responses to painful stimuli.

Thus, the functional roles of individual components of the opioid system continue to be elucidated by analysis of knockout mice. The μ-opioid receptor continues to be recognized as a predominant signaling receptor for both the affective and antinociceptive action of opioid agonism.

ACTIONS OF OPIOIDS ON TARGETS OTHER THAN OPIOID RECEPTORS

Molecular pharmacologic analyses have shown that opioids can interact with molecules other than the opioid receptors. In cardiac myocytes, morphine can inhibit voltage-dependent sodium (Na^+) current in a naloxone-insensitive manner, a finding suggesting the existence of a signal transduction mechanism that is not dependent on the opioid receptors.[81] Buprenorphine, a partial μ-opioid receptor agonist, also has a local anesthetic property and blocks voltage-gated Na^+ channels through the local anesthetic binding site.[82] Meperidine is an agonist of both μ and κ receptors. In addition, meperidine can block voltage-dependent Na^+ channels in amphibian peripheral nerves,[83] as well as in the *Xenopus* oocyte expression system.[84] Furthermore, meperidine exerts agonist activity at the α_{2B}-adrenoreceptor subtype.[85] Yamakura and associates have shown that high concentrations of opioids, including meperidine, morphine, fentanyl, codeine, and naloxone, directly inhibit the *N*-methyl-D-aspartate (NMDA) receptor expressed in *Xenopus* oocytes.[86] Methadone is clinically used as a racemic mixture of the *l* and *d* isomers. The opioid-like activity of the racemate seems to be almost entirely the result of *l*-methadone, whereas *d*-methadone acts as an NMDA antagonist.[87] The commercially available remifentanil solution (Ultiva), which contains glycine, directly activates the NMDA receptor expressed in *Xenopus* oocytes.[88] Furthermore, an electrophysiologic study in rat spinal cord showed that remifentanil hydrochloride does not directly activate NMDA receptors, the NMDA current recorded after application of Ultiva is related to the presence of glycine, and the glycine-induced NMDA current is potentiated by application of remifentanil hydrochloride through a pathway involving the μ-opioid receptor.[89] The serotonin type 3A ($5\text{-}HT_{3A}$) receptor, which is directly and indirectly linked to gastrointestinal motility, visceral pain, nausea, and vomiting, is competitively inhibited by morphine and hydromorphone, as well as naloxone; however, fentanyl-like opioids did not significantly affect activity of the 5-HT_{3A} receptor.[90,91] The mechanism for tramadol analgesia is complex and appears to be composed of two actions that include reuptake inhibition of the noradrenergic serotonergic system and activation of the μ-opioid receptor. Tramadol's analgesic effect is only partially reversed by the μ-opioid receptor antagonist, naloxone. Furthermore, tramadol also acts as an agonist of transient receptor potential vanilloid-1 (TRPV1) heterologously expressed in cultured cells.[92] Tramadol may activate TRPV1 in sensory neurons, followed by local release of vasoactive neuropeptides and marked desensitization of the afferent fibers. Inhibition of the nicotinic acetylcholine receptor by tramadol has also been reported.[93] It remains to be clarified which of these "off-target" actions of opioids have physiologic or clinical implications.

PHYSIOLOGIC ROLE OF NOCICEPTIN/ ORPHANIN FQ

Nociceptin or orphanin FQ is a 17-amino-acid peptide, the sequence of which resembles those of opioid peptides. Nociceptin or orphanin FQ precursor mRNA and peptide are present throughout the descending pain control circuits. In the spinal cord, nociceptin or orphanin FQ-receptor mRNA expression is stronger in the ventral horn than in the dorsal horn, but higher levels of ligand binding occur in the dorsal horn. Targeted disruption of the nociceptin or orphanin FQ receptor in mice had little effect on basal pain sensitivity in several measures, whereas targeted disruption of the N nociceptin or orphanin FQ precursor consistently elevated basal responses in the tail-flick test, findings suggesting an important role for nociceptin or orphanin FQ in regulating basal pain sensitivity.[94,95] Intrathecal injections of nociceptin or orphanin FQ have been shown to be analgesic[96]; however, supraspinal administration has produced hyperalgesia, antiopioid effects, or a biphasic hyperalgesic-analgesic response.[97] Nociceptin or orphanin FQ inhibits both pain-facilitating and analgesia-facilitating neurons in the RVM.[98] The effects of nociceptin or orphanin FQ on pain responses appear to depend on the preexisting state of pain in the animal. Involvement of nociceptin or orphanin FQ in physiologic functions such as regulation of feeding, body weight homeostasis, and stress response, and in psychiatric disorders such as depression, anxiety, and drug or alcohol dependence has also been reported.[99]

Systemic administration of nonpeptide nociceptin or orphanin FQ receptor agonists revealed that such compounds were effective analgesics in animal pain models. It was reported that a nociceptin or orphanin FQ receptor agonist, Ro64-6198, has antinociceptive and antiallodynic potency and efficacy without side effects of opioids such as itching, respiratory depression, and addiction in monkeys.[100] As nociceptin or orphanin FQ and opioid receptor agonists modulate pain by different targets, combining both mechanisms may constitute a novel approach for the development of innovative analgesics. Cebranopadol, a newly synthesized compound possessing nociceptin or orphanin FQ and opioid receptor agonist activity, exhibits highly potent and efficacious antinociceptive and antihyperalgesic effects in several rat models of acute and chronic pain (tail-flick, rheumatoid arthritis, bone cancer, spinal nerve ligation, diabetic neuropathy).[101] In a phase 1 clinical trial, it was shown that cebranopadol produced respiratory depression with a ceiling effect, in contrast to apnea produced by full μ-opioid receptor agonists.[102]

Expression of opioid receptors on peripheral blood mononuclear cells is controversial. Williams and associates reported that human peripheral blood mononuclear cells express the nociceptin receptor, but not μ-, δ-, or κ-opioid receptors.[103] Nociceptin, produced by the peripheral blood mononuclear cells, is involved in the control of immune functions.

Neurophysiologic Effects of Opioids

CHARACTERISTICS OF THE ANALGESIC ACTION OF OPIOIDS

In human beings, morphine-like drugs produce analgesia, drowsiness, changes in mood, and mental clouding. A significant feature of opioid analgesia is that it is not typically associated with loss of consciousness. When morphine in the same dose is given to a normal, pain-free individual, the experience may be unpleasant. The relief of pain by morphine-like opioids is relatively selective, in that other sensory modalities are not affected. Patients frequently report that the pain is still present, but that they feel more comfortable. It is also important to distinguish between pain caused by stimulation of nociceptive receptors and transmitted over intact neural pathways (nociceptive pain) and pain that is caused by damage to neural structures, often involving neural supersensitivity (neuropathic pain). Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain may respond poorly to opioid analgesics and require higher doses of drug.[104]

The analgesic effects, as well as side effects, of opioids vary greatly among individuals. A pharmacogenomic twin study has shown that the interindividual variations in opioid effects are likely the result of genetic and environmental factors.[105,106] Animal and human studies indicate the existence of sex-related differences in opioid-mediated behavior.[107] Sarton and associates examined the influence of morphine on experimentally induced pain in healthy volunteers, and demonstrated the gender differences in morphine analgesia, with greater morphine potency but slower speed of onset and offset in women.[108] In contrast, in a study examining interindividual variability in alfentanil analgesic sensitivity in experimental pain models in humans, no gender differences were detected.[109] In a study examining the effects of genetic factors on pain sensitivity, it was shown that males had higher pain thresholds in both thermal skin pain and muscle pressure pain than females.[110] The mechanism of the gender difference in pain sensitivity and opioid effects remains to be clarified.

The pharmacokinetic and pharmacodynamic characteristics of opioids often vary throughout the day, as demonstrated for oral morphine in chronic pain.[111] The duration of intrathecal sufentanil analgesia exhibited a temporal pattern, with 30% variation throughout the day in women in the first stage of labor.[112] Scavone and colleagues reported that the time of day of administration does not seem to influence duration of labor analgesia with spinal-epidural administration of fentanyl or with systemic hydromorphone administration.[113] The potential impact of chronobiology on clinical practice is not clear, and research on the influence of circadian rhythms on the actions of opioids is warranted.

Some controversy remains regarding analgesia produced by peripheral actions of opioids. One review concluded from meta-analysis that intraarticularly administered morphine has a definite but mild analgesic effect.[114] It may be dose dependent, and a systemic effect cannot be completely excluded. The addition of opioids in brachial plexus block improves the success rate and postoperative analgesia.[115] In contrast, the addition of sufentanil may not prolong the duration of brachial plexus block.[116]

Despite variations in effect ascribed to the type of pain stimuli, genetics, gender, time of administration, or site of action (central versus peripheral), opioids remain one of the most potent classes of analgesic drugs.

EFFECTS OF OPIOIDS ON CONSCIOUSNESS

Cortical acetylcholine originates in the basal forebrain and is essential for maintaining normal cognition and arousal. Injection of morphine to the substantia innominata or intravenous morphine administration significantly decreased acetylcholine release within the prefrontal cortex in the rat, and this effect may be the neurochemical basis of opioid-induced change in consciousness.[117] Although unconsciousness in humans can be produced with high doses of opioids alone, opioid-based anesthesia can be unpredictable and inconsistent.[118] Therefore, opioids are not suitable as sole intravenous induction agents.[119] The anesthetic potential of opioids was tested by measurement of MAC.[120] Fentanyl can reduce the MAC of isoflurane at skin incision in patients by at least 80%.[121] The relationship between the plasma fentanyl concentration and reduction in MAC is not linear, and fentanyl has a sub-MAC ceiling effect on reduction of the MAC of isoflurane. The MAC of sevoflurane was also dose dependently reduced by fentanyl, with 3 ng/mL resulting in a 61% reduction in MAC.[122] A ceiling effect was observed for MAC; 6 ng/mL fentanyl provided only an additional 13% reduction in the MAC of sevoflurane. Even potency ratios have been established for the “reduction of volatile anesthetic MAC” for most opioids such as sufentanil, fentanyl, remifentanil, and alfentanil. However, the MAC-reducing capabilities of the opioids are not complete; that is, these are not complete anesthetics. The opioids must be combined with other anesthetics to produce a “complete anesthetic.”[121,123-125] Esmolol, a short-acting β_1-receptor antagonist, significantly decreased the MAC of isoflurane in the presence of alfentanil, although it did not significantly affect this parameter in the absence of alfentanil.[126] The mechanism of the interaction is unknown. Epidural fentanyl infusion reduces the awakening concentration of isoflurane more than does intravenous fentanyl infusion despite the lower plasma concentration, possibly by modulating the afferent nociceptive inputs in the spinal cord.[127]

The MAC that prevents movement in response to laryngoscopy and tracheal intubation in 50% of patients (MAC-TI) is higher than the MAC that prevents movement in response to surgical incision (MAC). The MAC-TI of sevoflurane was 3.55% and was reduced markedly to 2.07%, 1.45%, and 1.37% by the addition of fentanyl 1, 2, and 4 μg/kg, respectively, with no significant difference in the reduction between 2 and 4 μg/kg, thus showing a ceiling effect.[128] The MAC that prevents sympathetic responses to surgical incision in 50% of patients (MAC-BAR) decreased with increasing concentrations of fentanyl in plasma, and the initial steep reduction followed by a ceiling effect.[122]

The bispectral index (BIS) is often used to determine the level of consciousness under anesthesia. In the presence of fentanyl, alfentanil, remifentanil, or sufentanil, loss of consciousness occurred at a lower effect-site concentration of propofol and at a higher BIS value as compared with propofol alone.[129] Furthermore, Wang and associates reported that infusion of remifentanil (0.1-0.4 μg/kg/min) did not significantly change the median effective concentration (EC_{50}) of propofol necessary to lower the BIS value to 50 or less.[130] These results suggest that the hypnotic effect of propofol is enhanced by analgesic concentrations of opioids without changes in the BIS value. Conversely, infusion of remifentanil (effect-site target concentrations of 0.25, 2.5, and 10 ng/mL), combined with propofol infusion adjusted to a BIS of approximately 60, dose dependently decreased the BIS, thus suggesting a sedative or hypnotic effect of remifentanil.[131] Response surface analysis showed considerable synergy between opioids and hypnotics for sedation and suppression of responses to various noxious stimuli.[132] In contrast to the effect of opioids administered during anesthesia on the BIS, the impact of chronic opioid use on BIS is unknown. It was recently reported that the end-tidal concentration of sevoflurane necessary to maintain the BIS under 50 was 0.84% for chronic opioid users who received a stable dose of oral morphine of at least 60 mg/day according to the morphine equivalent daily dose for at least 4 weeks, which was lower than for opioid-naïve patients (1.18%).[133]

Opioids administered as a mainstay of postsurgical pain management can inhibit sleep on the first night after surgery. However, the effects of opioids on sleep and circadian rhythm are not clearly understood. A human study demonstrated that an overnight constant infusion of remifentanil inhibited rapid eye movement sleep without suppressing the nocturnal melatonin surge, findings that may suggest a minimal effect of opioids on the circadian pacemaker.[134]

Taken together, perioperative opioids have consistently been shown to dose dependently reduce the MAC and are well known to synergize with hypnotics to produce sedation; however, their ability to effect the BIS may vary depending on the context of opioid administration.

HALLUCINATION

Opioid-induced hallucination is an uncommon yet significant adverse effect of opioid treatment, frequently attributed to underlying psychiatric disease or personality disorder rather than a direct neurobiologic effect of opioids.[135] Hallucinations attributed to opioids have been typically described as auditory, visual, or rarely, tactile hallucinations. Although many reports have cited morphine as the causative agent, there is no evidence that across a population, one particular class of opioid is associated with a lower incidence of hallucinations. Moreover, there are reports of fentanyl, methadone, tramadol, hydromorphone, buprenorphine, pentazocine, and/or oxycodone–associated hallucinations and/or changes in mental status. Nevertheless, accumulation of morphine metabolites, particularly morphine-3-glucoronide, has been linked to the development of neurologic phenomena.[136] Many hypotheses have been advanced to explain the etiology of opioid-induced hallucinations. One common feature of these hypotheses involves opioid-induced dopamine dysregulation. Overactivation of the dopaminergic pathways is thought to result in auditory and visual hallucinations.[137] The simplest treatment for opioid-induced hallucination is discontinuing opioid therapy if practical. There are reports describing the successful use of naloxone and κ-selective opioid antagonists in the treatment of hallucinations associated with schizophrenia, although such κ-selective agents are known to be associated with hallucinations in subjects or patients without a diagnosis of mental illness.[138]

ELECTROENCEPHALOGRAPHY

Increasing concentrations of inhaled anesthetics produce a continuum of electroencephalogram (EEG) changes and eventually result in burst suppression and a flat EEG. In contrast, a ceiling effect is reached with opioids. Once this ceiling has been obtained, increasing opioid dosage does not further affect the EEG.[139]

Although the potency and rate of equilibrium between plasma and brain are different among opioids, the effects of fentanyl, alfentanil, sufentanil, and remifentanil are consistent (Fig. 24.9).[140] Small doses of fentanyl (2-5 μg/kg) produce minimal EEG changes, whereas higher doses (30-70 μg/kg) result in high-voltage slow (δ) waves suggesting a state consistent with anesthesia. Although transient isolated (usually frontotemporal) sharp wave activity can be observed after large doses of fentanyl and other opioids, it is not generalized. In a study examining the effect of morphine (3-10 mg) on EEG in patients (14.8 ± 2.8 years) who stayed overnight for pain relief after otologic surgery, it was demonstrated that morphine reduced high-frequency β_1 (13.5-20 Hz) and β_2 (20-30 Hz) EEG powers and decreased coherence between frontal and occipital β_2 EEG activities compared to wakefulness and non–rapid eye movement sleep, indicating that morphine induced a deep sedative state (Fig. 24.10).[141] Khodayari-Rostamabad and associates studied the effect of remifentanil administration on resting EEG functional connectivity and its relationship to cognitive function and analgesia in healthy volunteers.[142] Remifentanil administration was associated with significant changes in functional cortical connectivity, which seem to disrupt the complex cortical network subserving normal brain function and can have the potential to be a biomarker for the sedative effects of opioids.

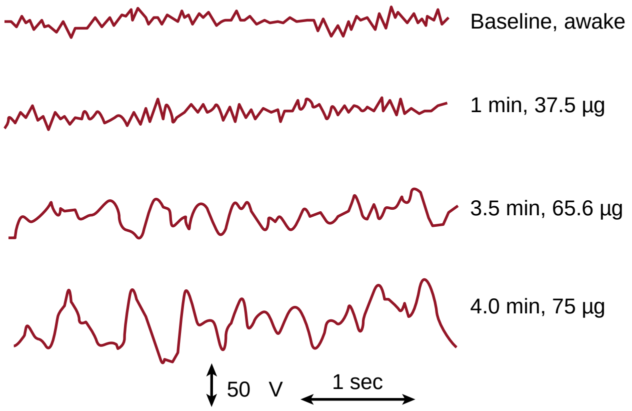

Fig. 24.9 Representative 4-s electroencephalogram (EEG) tracings during infusion of sufentanil (total dose shown in the right *column*). The awake baseline EEG consists of mixed β and α activity. At 1 minute, the EEG showed loss of β activity and the presence of primarily α waves (8-13 Hz). At 3.5 minutes, the EEG consisted of mixed θ (4-7 Hz) and δ (<4 Hz) waves, and at 4.0 min, it consisted of δ waves of high amplitude. (From Scott JC, Cooke JE, Stanski DR. Electroencephalographic quantitation of opioid effect: comparative pharmacodynamics of fentanyl and sufentanil. *Anesthesiology.* 1991;74:34–42.)

As an effect-site measure, EEG can be employed to assess onset of drug action and drug potency ratios. The spectral edge and serum concentration are closely parallel for remifentanil,[143] whereas a significant time lag is found for recovery of the spectral edge for fentanyl and sufentanil (Fig. 24.11).[144] In healthy volunteers, approximate entropy derived from a parietal montage showed significant correlation with remifentanil concentration, and it was shown to be appropriate for the assessment of the remifentanil effect on the EEG.[145] Potency ratios based on EEG studies are similar to those obtained from studies determining the plasma drug levels of each opioid necessary to reduce the MAC of isoflurane by 50%. Overall, opioids produce dose-dependent changes in the EEG that can mimic those of volatile anesthetics, however opioids show a ceiling effect at higher doses.

EVOKED RESPONSES

Because opioids do not appreciably alter sensory-evoked potentials elicited at the posterior tibial or median nerve, sensory-evoked potentials can be used for spinal cord function monitoring during anesthesia using opioids.[146] Although remifentanil produced dose-dependent reduction in auditory-evoked potentials,[147] it was also reported that remifentanil infusion (target plasma concentrations of 1, 2, and 3 ng/mL) did not affect evoked potential amplitudes and latencies.[148] In healthy human volunteers receiving 3 μg/kg fentanyl, amplitude and latency of motor-evoked responses to transcranial stimulation were not significantly affected.[149] This is consistent with the report by Kawaguchi and colleagues that intraoperative myogenic motor-evoked potential monitoring is feasible during isoflurane or sevoflurane anesthesia with fentanyl.[150]

Middle latency auditory-evoked potentials (MLAEPs) and their derivatives are increasingly used as a surrogate measure of the level of anesthesia. Changes in MLAEPs following the administration of opioids occur and may result from either a direct depressant effect of opioids on MLAEPs itself or an indirect effect reflecting the action of opioids in attenuating CNS arousal associated with noxious stimuli. Wright and associates examined the effect of remifentanil (1 or 3 μg/kg/min) on MLAEPs in tracheally intubated and nonintubated patients and showed that remifentanil has an effect on MLAEPs in attenuating the arousal associated with tracheal intubation but had no effect in the absence of a stimulus.[151] Similarly, Schraag and associates found no significant contribution of remifentanil alone on MLAEPs,

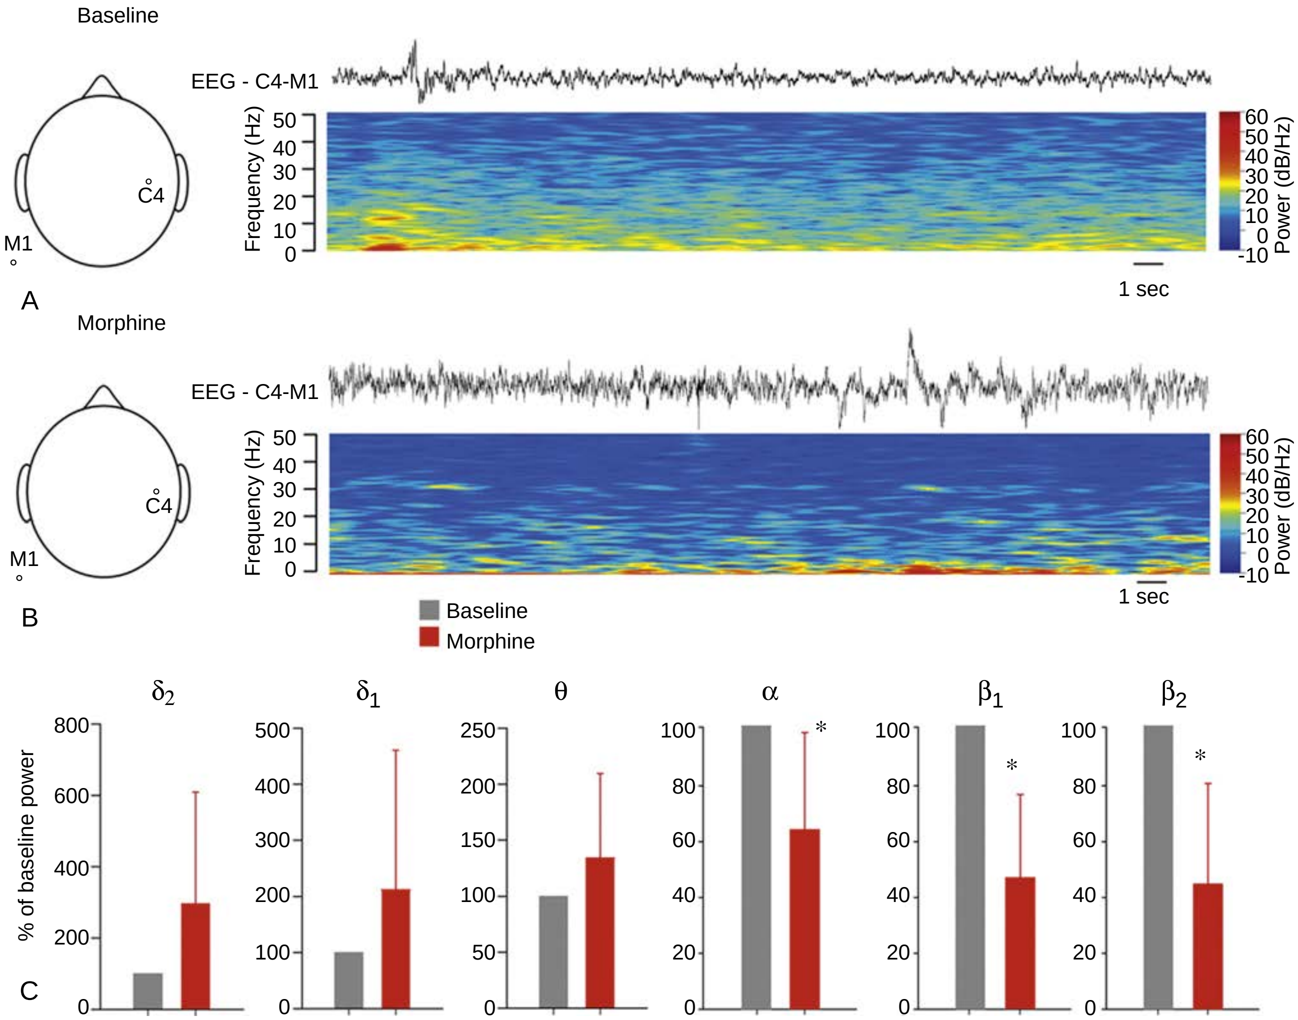

Fig. 24.10 Impacts of morphine on electroencephalography *(EEG)* spectral content. EEG activity of a representative 30-s epoch and power spectrograms of *C4-M1* (C4 = central electrode; M1 = mastoid electrode) derivation at baseline and after morphine administration. In a representative patient (A) and in the analyzed group data (B and C), high-frequency power (α, β_1, and β_2) was decreased by morphine. Mean data for 10 patients showed that morphine decreased α ($P = .039$, $n = 10$), β_1 ($P = .003$, $n = 10$), and β_2 ($P = .020$, $n = 10$) powers but did not change δ_2 ($P = .375$, $n = 10$), δ_1 ($P = .922$, $n = 10$), and θ ($P = .331$, $n = 10$) powers. Data are shown as mean ± 95% CI. *mean values significantly different from baseline with a $P < .05$. (From Montandon G, Cushing SL, Campbell F, et al. Distinct cortical signatures associated with sedation and respiratory rate depression by morphine in a pediatric population. *Anesthesiology*. 2016;125:889–903.)

whereas increasing the concentration of remifentanil led to a significant decrease of the calculated propofol effect-site concentrations necessary for unconsciousness.[152]

CEREBRAL BLOOD FLOW AND CEREBRAL METABOLIC RATE

Opioids generally produce modest decreases in cerebral metabolic rate and intracranial pressure (ICP), although the changes are influenced by the concomitant administration of other agents and anesthetic drugs, as well as by the patients' conditions. When vasodilation is produced by coadministered anesthetics, opioids are more likely to cause cerebral vasoconstriction. Opioids also decrease cerebral blood flow (CBF) when they are combined with nitrous oxide (N_2O). When opioids are administered alone or when the coadministered anesthetics cause cerebral vasoconstriction, opioids usually have no influence or result in a small increase in CBF.

Endogenous opioid activity is present in the cerebral arteries, although exogenously administered opioids were found to exert little effect on pial artery diameter in several animal models.[153] In the piglet, fentanyl, alfentanil, and sufentanil decreased arteriolar diameter in a dose-dependent naloxone-reversible manner.[154] In human volunteers, PET demonstrated that CBF changes induced by fentanyl are regionally heterogenous.[155]

In healthy volunteers, sufentanil (0.5 μg/kg intravenously [IV]) produces no significant effect on CBF.[156] Alfentanil (25-50 μg/kg IV), administered to patients receiving isoflurane (0.4%-0.6%)-N_2O anesthesia, produces minimal reductions in middle cerebral artery flow velocity.[157] A PET study in human volunteers showed that remifentanil induced dose-dependent changes in relative regional CBF in areas involved in pain processing, such as the lateral prefrontal cortex, inferior parietal cortex, and supplementary motor area.[158] In patients scheduled to undergo a supratentorial tumor surgical procedure and receiving N_2O,

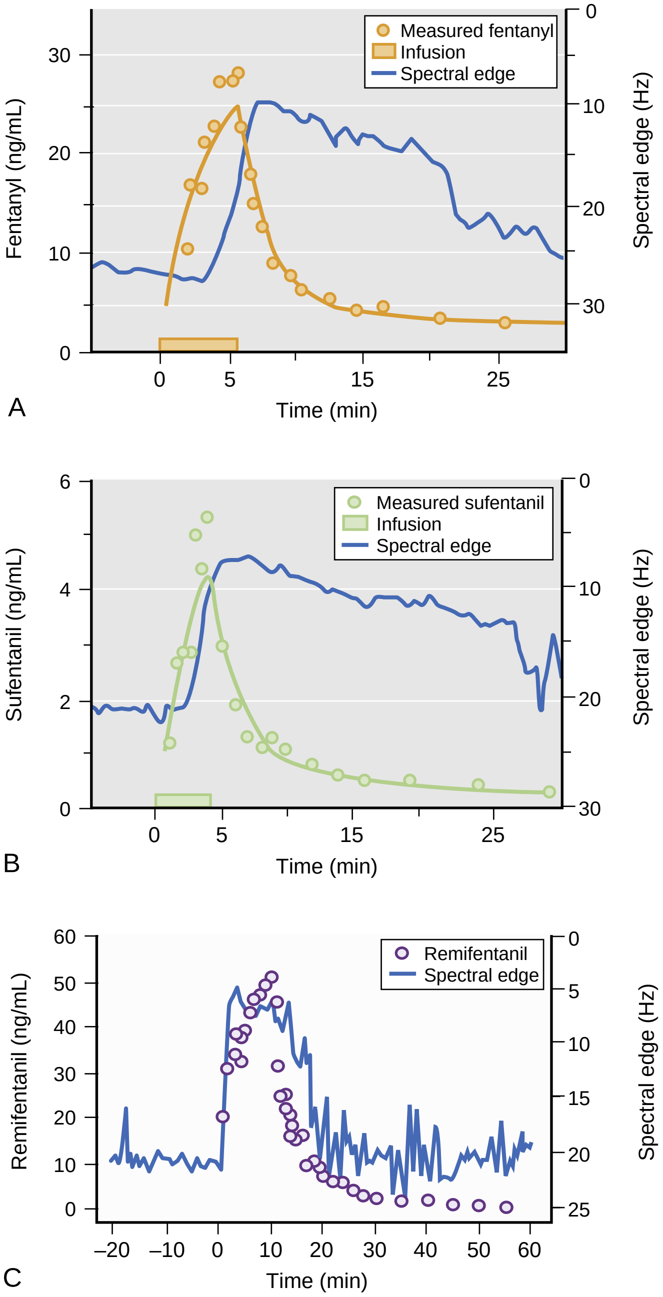

Fig. 24.11 Time course of spectral edge and serum opioid concentration. Fentanyl (A) and sufentanil (B) were infused at 150 μg/min and 18.75 μg/min, respectively. Remifentanil (C) was administered at 3 μg/kg/min for 10 minutes. The spectral edge changes lag behind the serum concentration changes in the case of fentanyl and sufentanil, whereas the spectral edge and serum concentration closely parallel in the cases of remifentanil. (From Scott JC, Ponganis KV, Stanski DR. EEG quantitation of narcotic effect: the comparative pharmacodynamics of fentanyl and alfentanil. *Anesthesiology*. 1985;62:234–241; and Egan TD, Minto CF, Hermann DJ, et al. Remifentanil versus alfentanil: comparative pharmacokinetics and pharmacodynamics in healthy adult male volunteers. *Anesthesiology*. 1996;84:821–833.)

remifentanil (1 μg/kg/min), similar to fentanyl (2 μg/kg/min), reduced CBF and did not significantly affect cerebrovascular carbon dioxide (CO_2) reactivity.[159]

Opioid-induced neuroexcitation and focal seizure activity can cause regional increases in brain metabolism. Regional increases in glucose use induced by high doses of alfentanil in the rat were associated not only with epileptiform activity but also with neuropathic lesions.[160] In humans, PET evaluation demonstrated that a 1 to 3 μg/kg/min infusion of remifentanil induces significant increase in the cerebral metabolic rate for glucose.[161] In summary, opioids, in general, do not significantly effect measures of CBF.

INTRACRANIAL PRESSURE

Opioids are generally thought to affect ICP minimally under conditions of controlled ventilation. When given with background anesthesia (isoflurane-N_2O), opioids do not cause significant increases in ICP undergoing craniotomy for supratentorial space-occupying lesions.[162,163] Opioid sedation does not alter ICP in patients with head injuries.[164] Light sedation with remifentanil (4.2 ± 1.8 μg/kg/h) does not result in higher ICP than that observed with propofol (4.3 ± 2.5 mg/kg/h) in patients undergoing stereotactic brain tumor biopsy, and cerebral perfusion pressure might be better preserved with remifentanil.[165]

Opioids may produce increases in ICP in patients undergoing craniotomy for excision of supratentorial space-occupying lesions, especially if intracranial compliance is compromised. In a study of patients with severe head injury who have preserved and impaired autoregulation, morphine (0.2 mg/kg) and fentanyl (2 μg/kg) moderately increased ICP, a finding suggesting that mechanisms other than vasodilation could be implicated in the opioid-induced ICP elevation.[166] Investigators also demonstrated no change in ICP in hydrocephalic children after administration of alfentanil (70 μg/kg).[167] Whether these discrepancies of the opioid effects on ICP reflect pressure assessment methods or the effects of other drugs is not clear. If opioids do increase ICP, whether cerebrovascular dilatation is directly induced by opioids or indirectly resulted from opioid-induced decrease in blood pressure is not known.

NEUROPROTECTION

Although certain early studies suggested potentially adverse effects of μ-opioid agonists on ischemic brain, other studies documented that certain opioid agents, such as the κ-agonists, can be neuroprotective in animal models of focal ischemia.[168] Investigators also showed that activation of δ-opioid receptors increases survival time of mice during lethal hypoxia.[169] An in vitro study using rat cerebellar brain slices demonstrated that pretreatment with morphine at clinically relevant concentrations induced acute neuroprotection mediated by activation of the δ_1-opioid receptors, activation of adenosine triphosphate (ATP)-sensitive K^+ channels, and free radical production in mitochondria.[170] In the rat focal ischemia model, fentanyl neither increased nor decreased brain injury compared with awake unanesthetized rats.[171] It was demonstrated that at a supraclinical concentration remifentanil had no pronecrotic effect but exerted ex vivo antiapoptotic action on the immature mouse brain, involving the opioid and NMDA receptors, and the mitochondrial-dependent apoptotic pathway.[172] A recent study reported that κ-opioid receptors were upregulated and played a critical role in brain ischemia and reperfusion in mice, and that κ-opioid receptor activation could potentially protect the brain and improve neurologic outcome via blood-brain barrier protection, apoptosis reduction, and inflammation inhibition.[173] Although there is contradicting evidence for a potential neuroprotection in animal models, there is no clear evidence for neuroprotective effects in humans.

MUSCLE RIGIDITY

Opioids can increase muscle tone and may cause muscle rigidity. The incidence of rigidity noted with opioid anesthetic techniques varies greatly because of differences in dose and speed of opioid administration, the concomitant use of N_2O, the presence or absence of muscle relaxants, and the patient's age. Opioid-induced rigidity is characterized by increased muscle tone that sometimes progresses to severe stiffness and associated clinical challenges (Table 24.4). Clinically significant opioid-induced rigidity usually begins just as, or after, a patient loses consciousness. Mild manifestations of rigidity, such as hoarseness, can occur in conscious patients. Vocal cord closure is primarily responsible for the difficult ventilation with bag and mask that follows the administration of opioids. Although opioids are generally thought to affect ICP minimally, it was demonstrated that alfentanil-induced rigidity can cause increase in ICP in rats.[174] Delayed or postoperative rigidity may be related to second peaks that can occur in plasma opioid concentrations, similar to the recurrence of respiratory depression.

The precise mechanism by which opioids cause muscle rigidity is not clearly understood. Muscle rigidity is not the result of a direct action on muscle fibers because it can be decreased or prevented by pretreatment with muscle relaxants. Mechanisms of opioid-induced muscle rigidity involving the CNS have been postulated. The nucleus raphe pontis within the reticular formation and the caudate nucleus within the basal ganglia have been implicated mechanistically.[175] Pharmacologic investigation using selective agonists and antagonists suggests that systemic opioid-induced muscle rigidity is primarily caused by the activation of central μ-receptors, whereas supraspinal δ_1 and κ_1 receptors may attenuate this effect.[176] Some aspects of opioid-induced catatonia and rigidity (increased incidence with age, muscle movements resembling extrapyramidal side effects) are similar to Parkinson disease and suggest similarities in neurochemical mechanisms. Patients with Parkinson disease, particularly if they are inadequately treated, may experience reactions such as dystonia following opioid administration.[177]

Pretreatment with or concomitant use of nondepolarizing muscle relaxants can decrease the incidence and severity of rigidity. Opioid-induced muscle rigidity can also be reversed with the μ-receptor antagonist naloxone. Induction doses of sodium thiopental and subanesthetic doses of diazepam and midazolam can prevent, attenuate, or successfully treat rigidity.

TABLE 24.4 Potential Problems Associated With Opioid-Induced Rigidity

System	Problem

NEUROEXCITATORY PHENOMENA

Fentanyl causes seizure activity seen on the EEG in animals, but EEG evidence of seizure activity after fentanyl, alfentanil, or sufentanil is generally lacking in humans. Remifentanil induced generalized tonic-clonic seizure-like activity in an otherwise healthy adult.[178] Morphine produces tonic-clonic activity after epidural and intrathecal administration.[179] Focal neuroexcitation on the EEG (e.g., sharp and spike wave activity) occasionally occurs in humans after large doses of fentanyl, sufentanil, and alfentanil.

The mechanisms underlying opioid-induced neuroexcitatory phenomena are not completely clear. Excitatory opioid actions may be related to coupling to mitogen-activated protein kinase cascades.[180] Local increases in CBF and metabolism are also of theoretic concern because prolonged seizure activity, even if focal, could lead to neuronal injury and/or cellular death. Fentanyl, alfentanil, and sufentanil in large doses also induced hypermetabolism and histopathologic alterations of the limbic system in rats.[181] Experimental study using excised mouse hippocampus showed that the proseizure effect of morphine is mediated by selective stimulation of the μ- and κ-opioid receptors but not the activation of the δ-opioid receptor.[182] In rats, midazolam, naloxone, and phenytoin prevented EEG seizure activity and histologically evident brain damage induced by large doses of fentanyl.[183]

Measurement of CBF by magnetic resonance imaging in human volunteers indicated that the cingulate cortex is the most susceptible to activation by remifentanil (0.05-0.2 μg/kg/min), and susceptibility is affected by the apolipoprotein E genotype.[184] These findings support the notion that neuroactivation of limbic areas by the perioperative use of opioids may have a role in the genesis of postoperative cognitive dysfunction.

PUPIL SIZE

Morphine and most μ− and κ−agonists cause constriction of the pupil by an excitatory action on the parasympathetic nerve innervating the pupil. Light induces excitation of the Edinger-Westphal nucleus leading to pupillary constriction, which is inhibited by hypercarbia, hypoxia, and nociception. Opioids release the effect of inhibitory neurons on the Edinger-Westphal nucleus, resulting in papillary constriction (Fig. 24.12).[185] After intravenous administration of morphine (0.125 mg/kg) in one report, a 26% decrease in pupil diameter occurred at 1 hour, and a period of more than 6 hours was necessary for complete recovery of pupil diameter.[186] The pupillary dilatation reflex has been successfully used to assess the analgesic component of a balanced anesthetic regimen. The pupillometer may be a valuable tool to

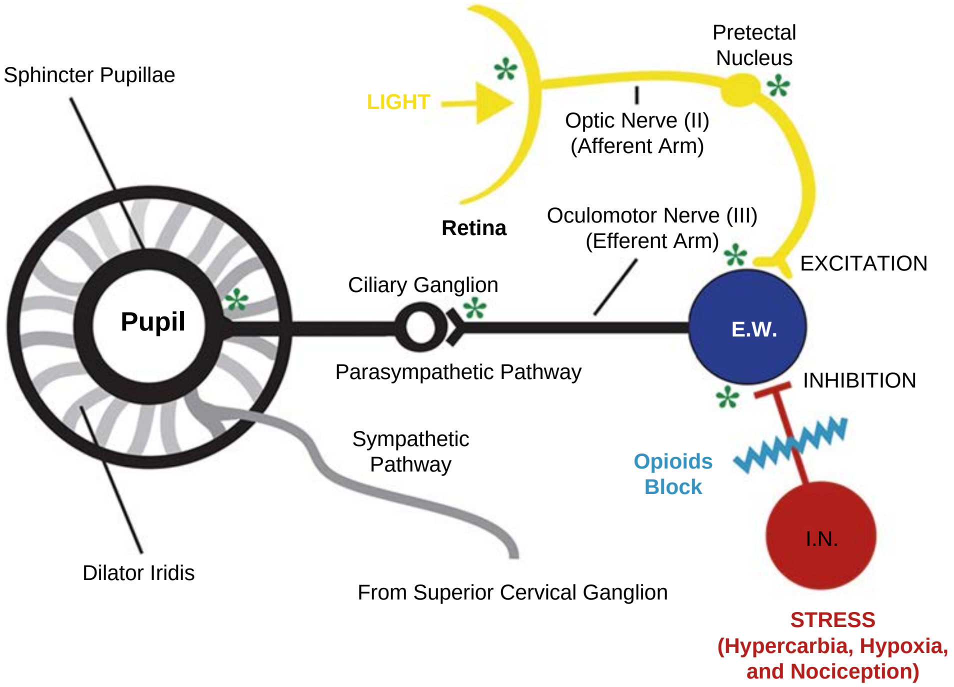

Fig. 24.12 Pathways and nerve centers that control pupil size and the pupillary light reflex in humans. *Colored* structures are the central nerve centers and pathways that modify the pupillary light reflex. Edinger-Westphal *(E.W.)* nucleus neurons are pacemaker cells that are modified by excitatory and inhibitory inputs. Opioids block the inhibition of the EW nucleus. Green asterisks (*) show locations where hypercarbia, hypoxia, and opioids might potentially interfere with the light reflex. * = locations where hypercarbia, hypoxia, and opioids might potentially interfere with the light reflex. *IN*, Inhibitory neuron. guide morphine administration in the immediate postoperative period.[187] A prospective randomized study evaluated the impact of intraoperative pupillometry monitoring on perioperative opioid consumption in major gynecologic surgery. It was demonstrated that the use of pupillometry to guide intraoperative analgesia reduced intraoperative remifentanil consumption and postoperative morphine requirements.[188] Pupillary unrest is the fluctuation in pupil diameter, and pupillary unrest under ambient light (PUAL) is present even in well-rested individuals. Although the underlying mechanisms are unknown, PUAL is depressed by opioids. Administration of fentanyl to healthy volunteers diminishes PUAL, and the decrease is proportionally larger than the change in pupil diameter.[189] The pretreatment magnitude of PUAL is correlated with the analgesic response to opioid therapy, and patients who exhibit higher levels of PUAL change after opioid administration have a more beneficial analgesic effect from opioids.[190]

Pupillary constriction represents a well-known phenomenon following opioid administration and the use of pupillometry may help guide intraoperative opioid dosing to optimize analgesia.

THERMOREGULATION AND SHIVERING

Opioid-based anesthesia probably reduces thermoregulatory thresholds to a degree similar to that of the potent inhaled anesthetics.[191] However, meperidine is unique among opioids in its ability to effectively terminate or attenuate shivering. The antishivering effect of meperidine is primarily related to a reduction in the shivering threshold,[192] and seems to be mediated by meperidine's activity on the κ receptor.[193] However, the relatively specific κ-receptor agonist, nalbuphine, did not show significant antishivering activity.[194] Meperidine exerts agonist activity at the α_{2B}-adrenoreceptor subtype, a finding suggesting the involvement of this action in the antishivering action of meperidine.[85] Alfentanil, morphine, and fentanyl are not as effective as meperidine in the treatment of postoperative shivering. However, alfentanil and nefopam, a centrally acting analgesic, additively reduce the shivering threshold in humans.[195] Tramadol (0.5 mg/kg) suppressed postepidural anesthetic shivering in parturients as effectively as meperidine (0.5 mg/kg).[196] A quantitative systematic review of randomized controlled trials found that meperidine 12.5 to 35 mg and tramadol 35 to 220 mg were more effective than control for parenteral pharmacologic interventions for the prevention of postoperative shivering.[197]

Remifentanil is associated with an increased incidence of postanesthetic shivering, which is not related with intraoperative hypothermia. The higher incidence of postanesthetic shivering with higher doses of remifentanil probably reflects acute opioid tolerance and stimulation of the NMDA receptors.[198] A small dose of ketamine, 0.5 mg/kg at induction of anesthesia followed by infusion at 0.3 mg/kg/hour, can prevent remifentanil-induced postanesthetic shivering.

PRURITUS

Opioid-induced pruritis is one of several perpetual challenges associated with opioid-based analgesia. With the possible exception of morphine, histamine release, once thought to underlie this phenomenon, is not causative because non-histamine-releasing opioids also produce pruritus. Both central and peripheral nervous system mechanisms have been explored. Facial itching may not necessarily be a manifestation of direct opioid action at the level of the trigeminal nucleus, but rather, it may be a reflection of opioid-triggered neural transmission at a distant site. It is not known why the face is prone to pruritus even after spinal opioids. Interestingly, pruritus due to cholestasis is ameliorated by opioid antagonists.[199] Intrathecal morphine-induced itching in monkeys was suggested to be mediated by the μ receptor.[200] Activation of a μ-opioid receptor isoform MOR1D[11] by morphine induced activation of the gastrin-releasing peptide receptor that heterodimerized with MOR1D, thus resulting in activation of phospholipase β3 and intracellular Ca^{2+} increase in neurons leading to itch sensation in mice.[201]

Naloxone reverses opioid-induced itching, but opioid antagonists are not ideal therapeutic agents against pruritus because opioid analgesia is often reversed by these agents. A subcutaneous administration (12 mg) of methylnaltrexone bromide, a peripherally acting μ-opioid antagonist, did not reduce the overall severity or incidence of pruritus in women having elective cesarean section under spinal anesthesia with intrathecal morphine 100 μg, suggesting that peripheral mechanisms do not significantly contribute to spinal opioid-induced pruritus.[202] Ondansetron, a serotonin 5-HT_3 receptor antagonist has been proposed to treat spinal or epidural morphine-induced pruritus,[203] and a meta-analysis has demonstrated that prophylactic use of 5-HT_3 antagonists significantly reduced the severity and the need for treatment of pruritus.[204] Another meta-analysis showed that prophylactic intravenous administration of 8 mg ondansetron does not decrease the incidence of fentanyl- or sufentanil-induced pruritus but may decrease the need for pruritus rescue medication.[205] The application of mixed or partial opioid agonists, such as nalbuphine and butorphanol, are growing in popularity as antipruritics because they may partially antagonize μ receptor function with intact κ actions to maintain analgesia.[206] In fact, activation of the κ-opioid receptor inhibits pruritus evoked by subcutaneous and intrathecal morphine in animal models.[207]

Other agents that have been investigated include pentazocine (15 mg), an agonist of the κ-opioid receptor and partial agonist of the μ-opioid receptor. Pentazocine has been found to be superior to 4 mg of ondansetron for the treatment of pruritus induced by intrathecal morphine in parturients undergoing cesarean delivery.[208] It was recently reported that the antipruritic effect of κ-receptor agonists may not require interaction between the κ receptor and β-arrestins.[209] Tenoxicam, a nonsteroidal antiinflammatory drug (NSAID), was reported to be effective for pruritus induced by epidural fentanyl.[210] Other approaches include intravenous administration of droperidol (1.25 mg), propofol (20 mg), or alizapride (100 mg), which reduced the incidence of pruritus induced by the use of morphine 0.2 mg intrathecally in patients undergoing cesarean section under spinal anesthesia.[211] Preoperative gabapentin prevents pruritus induced by intrathecal morphine in patients undergoing lower limb surgery with spinal anesthesia.[212]

As opioid-induced pruritis continues to be a clinical challenge, current strategies have shifted away from the consequences of histamine release (morphine) and are focused on exploiting partial blockade/activation of the μ-opioid receptor, activation of the κ-receptor, and non-opioid receptor pathways.

OPIOID-INDUCED HYPERALGESIA

There is growing evidence that opioid-induced hyperalgesia (OIH) can represent a major adverse effect of opioid administration, especially when driven by potent formulations and escalating dosages. Experimentally, opioids have elicited hyperalgesia in animal models after repeated opioid administration or continuous delivery.[213] A systematic review to evaluate the clinical implication of OIH demonstrated that high intraoperative doses of remifentanil are associated with small but significant increases in acute pain after surgery as assessed by: pain intensity at rest 24 hours after surgery, 24-hour morphine use, pain intensity on movement, and hyperalgesia measured after an operation.[214] In a randomized, double-blind, crossover study with 24 healthy male volunteers, it was demonstrated that when compared with low-dose (1 μg/kg) fentanyl, high-dose fentanyl (10 μg/kg) increased the area of hyperalgesia from 4.5 to 6.5 hours after fentanyl administration. This result suggests that fentanyl can also produce OIH in humans.[215]

OIH was shown to be due to spinal sensitization to glutamate and substance P.[216] Activation of glycogen synthase kinase-3β (GSK-3β) contributes to remifentanil-induced hyperalgesia by regulating NMDA receptor plasticity in the spinal dorsal horn,[217] and further demonstrated that GSK-3β inhibition prevented remifentanil-induced postoperative hyperalgesia via regulating α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) expression and function in the spinal dorsal horn.[218] Importantly, abrupt withdrawal of opioid administration may also contribute to induction of OIH, although its mechanism is not clear. In contrast to the high incidence of hyperalgesia induced after abrupt withdrawal of remifentanil (administered at 2.5 ng/mL for 30 minutes), no hyperalgesia was observed after gradual withdrawal by 0.6 ng/mL every 5 minutes.[219]

There have been reports that OIH and subsequent acute opioid tolerance can be prevented by ketamine, suggesting the involvement of the NMDA receptor.[220,221] Methadone is unique in possessing both μ-opioid receptor activating and NMDA antagonist properties. Opioid-induced hyperalgesia resulted from the presence in the racemate of the *l*-methadone (μ-opioid agonist) and was antagonized by the presence of the *d*-methadone (NMDA antagonist).[222] Low-dose buprenorphine (25 μg/h for 24 h), an opioid with NMDA antagonist activity, in patients receiving remifentanil infusion during major lung surgery prevented postoperative secondary hyperalgesia.[223] Butorphanol (0.2 μg/kg) was also effective for prevention of postoperative hyperalgesia after laparoscopic cholecystectomy performed with remifentanil (0.3 μg/kg/min).[224] N_2O, an inhalation anesthetic, is an effective NMDA antagonist. Intraoperative 70% N_2O administration significantly reduced postoperative opioid-induced hyperalgesia in patients receiving propofol (approximately 120 μg/kg/min) and remifentanil (0.3 μg/kg/min).[225] A randomized, double-blind, prospective study showed that a relatively high dose of remifentanil (0.2 μg/kg/min) enhances periincisional hyperalgesia in patients undergoing thyroidectomy, and intraoperative magnesium sulfate (30 mg/kg at induction followed by 10 mg/kg/h) can prevent remifentanil-induced hyperalgesia.[226]

Other strategies have focused on the upregulation of spinal cyclooxygenase-2 (COX-2) and increased prostaglandin E2 release in the spinal cord after morphine withdrawal in rats.[227] In humans, hyperalgesia after a 30-minute intravenous infusion of remifentanil (0.1 μg/kg/min) can be prevented by administration of parecoxib, a COX-2 inhibitor, before remifentanil infusion,[228] suggesting the involvement of COX-2 in OIH. Alternatively, it was reported that an ultra-low dose of naloxone blocked remifentanil-induced hyperalgesia but did not change opioid tolerance in rats under inhaled anesthesia, and that the MAC increase associated with hyperalgesia was also blocked by naloxone.[229] In patients undergoing elective thyroid surgery, intraoperative use of naloxone (0.05 μg/kg/h) reduced postoperative hyperalgesia after remifentanil infusion of 4 ng/mL.[230]

Genetic variants of the β_2-adrenergic receptor gene may explain some part of the differences between various strains of mice to develop OIH, and the selective β_2-adrenergic receptor antagonist butoxamine was shown to dose dependently reverse OIH.[231] In mice, systemic or intrathecal injection of the 5-HT_3 receptor antagonist, ondansetron, was shown to prevent or reverse opioid-induced tolerance or hyperalgesia.[232]

Interestingly, the occurrence of OIH might be affected by general anesthetics coadministered with opioids. When women undergoing breast cancer surgery were anesthetized with sevoflurane or propofol to keep BIS value at 40 to 50, postoperative hyperalgesia induced by intraoperative remifentanil infusion (effect-site target 4 ng/mL) was significant with sevoflurane anesthesia, but not apparent with propofol anesthesia.[233]

A follow-up study on the postoperative course of cardiac surgery demonstrated that intraoperative remifentanil was predictive for chronic thoracic pain 1 year after surgery in a dose-dependent manner.[234] It can be anticipated that hyperalgesia during the perioperative period is linked to peripheral and central pain sensitization and thereby correlates with the development of postoperative chronic pain.[235] This suggests that hyperalgesia due to remifentanil in the early postoperative period may explain the higher incidence of chronic pain.

Overall, human data generally support the existence of OIH in a few specific settings. Clinically relevant mechanisms of OIH include involvement of the NMDA receptor with ketamine as an appealing remedy. Although all potent opioids such as fentanyl are apparently capable of inducing OIH, ultrapotent opioid agonists such as remifentanil may pose even greater risks. The conditions under which OIH is expressed should be clarified and the extent of its clinical significance remains to be elucidated.[236]

Respiratory Effects of Opioids

The respiratory depressant actions of opioids represent their most serious adverse effect. Although some early studies indicated the involvement of both μ- and δ-opioid receptors, activation of the μ-opioid receptor in the caudal medullary raphe region, which is important for regulating pain and respiration, inhibits the ventilatory response to hypercapnia in anesthetized rats.[237] Furthermore, administration of morphine or M6G did not produce significant respiratory depression in the μ-opioid receptor knockout mice.[238] Polymorphism of the μ-opioid receptor at nucleotide position 118, which is known to affect M6G-induced analgesia, does not significantly change the susceptibility of respiratory depressive effect of M6G.[19] This result suggests that analgesia and respiratory depression may be mediated by different signal transduction mechanisms activated by the μ-opioid receptor.

EFFECTS ON AIRWAYS

The antitussive actions of opioids are well known and central in origin. Opioids blunt or eliminate somatic and autonomic responses to tracheal intubation. They allow patients to tolerate endotracheal tube placement without coughing or "bucking." Conversely, two successive doses of 1.5 μg/kg fentanyl did not effectively prevent laryngospasm in children aged 2 to 6 years old who were anesthetized with sevoflurane.[239] Opioids can also help avoid increases in bronchomotor tone in asthma. In addition, fentanyl also has antimuscarinic, antihistaminergic, and antiserotoninergic actions and may be more effective than morphine in patients with asthma or other bronchospastic diseases.

Nevertheless, several studies have reported a depressant effect of morphine on respiratory mucus transport, which is one of the most important defenses against respiratory tract infections. However, morphine had no effect on the beating frequency of nasal cilia in vitro.[240] Opioids can affect pharyngeal function, airway protection, and coordination of breathing and swallowing. A sedative dose of morphine (0.1 mg/kg) was associated with increased incidence of pharyngeal dysfunction and discoordinated breathing and swallowing, a combination impairing airway protection and potentially increasing the risk for pulmonary aspirations.[241]

More potent opioids such as remifentanil (effect-site concentration of 2 ng/mL) can suppress coughing induced by extubation after propofol or sevoflurane anesthesia.[242] In contrast, fentanyl, sufentanil, and alfentanil curiously elicit a brief cough in up to 50% of patients when the drug is injected by intravenous bolus. Fentanyl, administered through a peripheral intravenous cannula, provoked cough when it was injected rapidly, but the incidence of cough decreased significantly as the injection time was increased,[243] as well as by the administration of 1.5 mg/kg lidocaine 1 minute before fentanyl administration.[244] A meta-analysis showed that the lowest effective dose of lidocaine on the risk of opioid-induced cough was 0.5 mg/kg.[245] It was also reported that preemptive use of fentanyl 25 μg, administered 1 minute before bolus injection of fentanyl (125 or 150 μg), can effectively suppress fentanyl-induced cough.[246] Propofol, α_2 agonists (clonidine, dexmedetomidine), inhalation of β_2 agonists (terbutaline, salbutamol), and NMDA-receptor antagonists (ketamine, dextromethorphan) were also effective for suppression of fentanyl-induced cough.[247] A prospective randomized controlled study demonstrated that a huffing maneuver, consisting of a forced expiration against open glottis, just before intravenous fentanyl administration significantly reduced the incidence and severity of fentanyl-induced coughing in the majority of the patients.[248] Li and associates reported that nonsmoking women undergoing gynecological surgery who develop fentanyl-induced cough during induction of anesthesia have a higher incidence of postoperative nausea and vomiting (PONV).[249]

In summary, opioids engender potent antitussive properties that can help blunt airway responsiveness to endotracheal intubation. However, depending on the class of opioid and rate of administration, they may evoke a brief cough that can be subverted through the use of preadministered agents such as lidocaine. Ultimately, caution should be exercised in the administration of opioids as they can also interfere with protective aspects of airway physiology.

RESPIRATORY DEPRESSION

The lack of adequate pain relief can cause shallow respiration leading to postoperative respiratory dysfunction including atelectasis, and therefore opioids can serve as a foundational component of postoperative analgesia to prevent or correct respiratory impairment. However, opioids can also dose dependently depress respiration, representing the most feared adverse effect. The incidence of opioid-induced respiratory depression varies from 0.1% to 37%, depending on the route of opioid administration, the type of opioid, the definition and method of monitoring opioid-induced respiratory depression, and the prospective versus retrospective nature of the study, and is a significant cause of death and brain damage in the perioperative period.[250]

Opioids activating the μ receptor cause dose-dependent depression of respiration, primarily through a direct action on brainstem respiratory centers.[251] The stimulatory effect of CO_2 on ventilation is significantly reduced by opioids. Hypercapnic responses can be separated into central and peripheral components. In one report, morphine-induced changes in the central component were equal in men and women, whereas changes in the peripheral component were larger in women.[252] In addition, the apneic threshold and pressure of end-tidal carbon dioxide ($PETCO_2$) are increased by opioids (Fig. 24.13). Opioids also decrease hypoxic ventilatory drive.

Respiratory rate is usually drastically decreased in opioid overdose, although hypoxic CNS insult can counter this effect. The prolonged expiratory time in the respiratory cycle induced by opioids frequently results in greater reductions in respiratory rate than in tidal volume. Monitoring of breath intervals can sensitively detect fentanyl-induced respiratory depression and can be used as a measure of dynamic opioid effect.[253] High doses of opioids usually eliminate spontaneous respirations without necessarily producing unconsciousness. Patients receiving high doses of opioids may still be responsive to verbal command and often breathe when they are directed to do so.

Peak onset of respiratory depression after an analgesic dose of morphine is slower than after comparable doses of fentanyl, and respiratory depression induced by small doses of morphine usually lasts longer than after equipotent doses of fentanyl. Plasma fentanyl concentrations of 1.5 to 3.0 ng/mL are associated with significant decreases in CO_2 responsiveness. With higher doses of fentanyl (50-100 μg/kg), respiratory depression can persist for many hours. When moderately large doses (20-50 μg/kg or greater) of fentanyl are used, the potential need for postoperative mechanical ventilation should be anticipated. The effects of remifentanil are attenuated rapidly and completely within 5 to 15 minutes following termination of its administration. In healthy humans, the EC_{50} for depression of minute ventilation with remifentanil and alfentanil was 1.17 ng/mL and 49.4 ng/mL, respectively.[254] In healthy volunteers, fentanyl 1 μg/kg and remifentanil 0.5 μg/kg had similar maximum decreases in minute ventilation (~50%), but the onset of and recovery from ventilatory depression were faster with remifentanil.[255] Naloxone has been accepted as a standard therapy for opioid-induced respiratory depression. However, reports have noted naloxone-resistant respiratory depression after intrathecal morphine administration.[256]

A major component of the excitatory synaptic drive necessary for respiratory rhythmogenesis and activation of respiratory motoneurons is *via* the amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA) type of glutamate receptors.[257] This finding has led to investigations of ampakine (positive modulators of AMPA receptors) therapy to alleviate opioid-induced respiratory depression.[258] 5-HT released from the raphe nuclei potently alters the excitability of respiratory motoneurons, the preBötzinger complex (preBötC), and other brainstem respiratory nuclei. The activation of $5\text{-}HT_{1A}$ receptors with befiradol alleviates fentanyl-induced respiratory depression in rats.[259] PreBötC, the main region of respiratory rhythm–pattern generation, is the main target of opioid-induced respiratory depression.

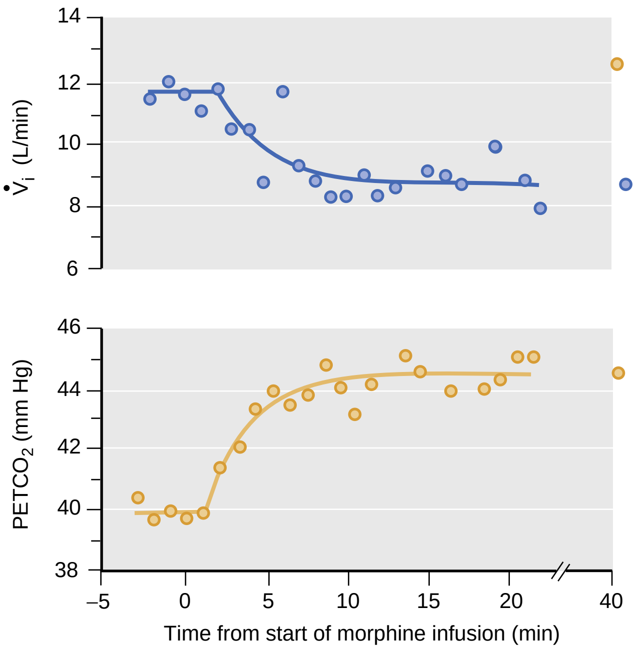

Fig. 24.13 Influence of morphine administration (bolus dose of 100 μg/kg given at the start of the infusion [0 minute], followed by a continuous infusion of 30 μg/kg/h) on resting inspired minute ventilation *(V_i)* and resting pressure of end-tidal carbon dioxide *($PETCO_2$)* in a single subject. A one-component exponential was fitted to the data. The estimated time constant for the V_i data is 3.0 minutes and for $PETCO_2$ data is 2.6 minutes. The time delays are between 1 and 2 minutes. (From Sarton E, Teppema L, Dahan A. Sex differences in morphine-induced ventilatory depression reside within the peripheral chemoreflex loop. *Anesthesiology*. 1999;90:1329–1338.)

However, it has been demonstrated that preBötC partially mediates opioid effects on respiratory phase timing, but does not mediate the opioid-induced depression of respiratory rate.[260] By the use of knockout mice and pharmacologic approaches, G-protein–gated inwardly rectifying κ channels were shown to contribute to respiratory depression by μ-opioid receptors and opioids.[261] In healthy humans, GAL021, a calcium-activated potassium (BKCa) channel blocker possessing a stimulatory effect on ventilation at the carotid bodies, was preliminarily shown to reverse alfentanil-induced respiratory depression.[262]

FACTORS AFFECTING OPIOID-INDUCED RESPIRATORY DEPRESSION

Many factors affect the magnitude and duration of opioid-induced respiratory depression (Box 24.2).

Older patients are more sensitive to the anesthetic and respiratory depressant effects of opioids and experience higher plasma concentrations of opioids administered on a weight basis. In addition, morphine can produce greater respiratory depression on a weight basis in neonates than adults, because morphine easily penetrates the brain of neonates and infants with incomplete blood-brain barriers.

The respiratory depressant effects of opioids are increased or prolonged (or both) when these drugs are administered with other CNS depressants, including potent inhaled anesthetics, alcohol, barbiturates, benzodiazepines, most intravenous sedatives, and hypnotics. However, droperidol, scopolamine, and clonidine do not enhance the respiratory depressant effects of fentanyl or other opioids. Curiously, Setnik and associates observed a decrease in end-tidal CO_2 when 0.7 g/kg ethanol was administered in addition to 80 mg oral morphine, suggesting a stimulatory effect of ethanol on opioid-induced respiratory depression.[263] However, it was reported that ethanol (1 g/L of breath ethanol concentration) caused a significant increase in the apneic events and increased end-tidal CO_2 induced by 20 mg oxycodone per os in opioid-naïve healthy volunteers.[264]

Although opioid action is usually dissipated by redistribution and hepatic metabolism, rather than by urinary excretion, the adequacy of renal function may influence the duration of opioid activity. In renal insufficiency, the respiratory depressant properties of morphine and hydromorphone, as well as of the morphine metabolite M6G, become evident as these accumulate.

Hypocapnic hyperventilation enhances and prolongs postoperative respiratory depression after fentanyl (10 and 25 μg/kg). Intraoperative hypercarbia produces the opposite effects. Possible explanations for these findings include increased brain opioid penetration (increased un-ionized fentanyl with hypocarbia) and removal (decreased CBF with hypocarbia). In patients who hyperventilate because of anxiety or pain, even small doses of intravenous opioids can result in transient apnea because of acute shifts in apneic thresholds. Respiratory depression by remifentanil (50 μg infused over 60 seconds) was more pronounced in hyperoxia (inhaling 50% O_2) than normoxia as determined by minute ventilation, end-tidal PCO_2, and respiratory rate.[265] During hyperoxia, respiratory depression may be masked when measuring SpO_2 as pulse oximetry remains in normal values during the first minutes of respiratory depression.

All opioid agonists with a longer plasma half-life than naloxone have a hypothetical potential to show renarcotization with time, especially when a bolus dose of naloxone is used to treat opioid-induced respiratory depression.

Overall, opioids exert their primary respiratory depressant effects through μ-receptor activation in the brainstem respiratory center, although other pathways have been defined. Dose-dependent opioid respiratory depression increases the apneic threshold, and reduces the respiratory stimulatory drive of CO_2 and hypoxia. Research efforts to block or reverse opioid-induced respiratory depression are ongoing and include a focus on AMPA, 5-HT_{1A}, and calcium-activated potassium channels. The μ-receptor antagonist, naloxone, continues to be the most commonly used clinical intervention to reverse opioid-induced respiratory depression, however its effectiveness may be limited if the administered opioid has a greater binding affinity and/or half-life than naloxone.

BOX 24.2 **Factors Increasing the Magnitude and/or Duration of Opioid-Induced Respiratory Depression**

- High dose
- Sleep
- Old age
- Central nervous system depressant
  - Inhaled anesthetics, alcohol, barbiturates, benzodiazepines
- Renal insufficiency
- Hyperventilation, hypocapnia
- Respiratory acidosis
- Decreased clearance
  - Reduction of hepatic blood flow
- Secondary peaks in plasma opioid levels
  - Reuptake of opioids from muscle, lung, fat, and intestine
- Pain

Cardiovascular Effects of Opioids

Numerous reports have demonstrated that large doses of opioid, administered as the sole or primary anesthetic, result in hemodynamic stability throughout the operative period. This remarkable physiologic state is a result of a number of complementary mechanisms.

NEUROLOGIC MECHANISMS

Key areas of the brainstem that integrate cardiovascular responses and maintain cardiovascular homeostasis are the nucleus solitarius, the dorsal vagal nucleus, the nucleus ambiguous, and the parabrachial nucleus. The nucleus solitarius and parabrachial nucleus play an important role in the hemodynamic control of vasopressin secretion. Enkephalin-containing neurons and opioid receptors are distributed in these regions. The direct administration of μ-agonists into the CNS of rats most commonly, but not always, produces hypotension and bradycardia.[266] The ventrolateral PAG region, a key central site mediating opioid analgesia, also affects hemodynamic control.[267] In addition, opioids can modulate the stress response through receptor-mediated actions on the hypothalamic-pituitary-adrenal axis. Most opioids reduce sympathetic and enhance vagal and parasympathetic tone. Patients who are volume depleted, or individuals depending on high sympathetic tone or exogenous catecholamines to maintain cardiovascular function, are predisposed to hypotension after opioid administration.

The predominant and usual effect of opioids on heart rate is bradycardia resulting from stimulation of the central vagal nucleus. Blockade of sympathetic actions may also play a role in opioid-induced bradycardia. Meperidine, in contrast to other opioids, rarely results in bradycardia, but it can cause tachycardia. Tachycardia after meperidine may be related to its structural similarity to atropine, to normeperidine, its principal metabolite, or to early manifestations of its toxic CNS effects.

CARDIAC MECHANISMS

The direct cardiac actions of opioids, in particular the effects on myocardial contractile mechanisms, are significantly less pronounced than are those of many other intravenous and inhaled anesthetics. However, opioid receptors exist in cardiac myocytes of several species.

Contractility

Morphine decreases Ca^{2+} transients but not cardiac contraction and enhances myofilament Ca^{2+} sensitivity through the action on the δ_1-opioid receptor expressed in the heart.[268] In rabbit ventricular myocytes, morphine prolonged action potential duration by increasing L-type Ca^{2+} current, an effect mediated by δ- and κ-opioid receptors, and hyperpolarized cardiac resting membrane potential by increasing the inwardly rectifying K^+ current, which is not mediated by opioid receptors.[269] Conversely, investigators demonstrated that morphine decreased the isometric force of contraction in atrial muscles from nonfailing and failing human hearts through a naloxone-insensitive mechanism.[270] Fentanyl produces little or no change in myocardial contractility.[271] Usually, most hemodynamic variables remain unchanged after large doses of fentanyl. Alfentanil, at concentrations achieved in clinical practice, increases contraction in ventricular cells by a mechanism involving an increase in the sensitivity of the contractile apparatus to Ca^{2+}.[272] The negative inotropic effect of tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) on ventricular myocytes caused by disruption of sarcoplasmic reticulum Ca^{2+} handling and Ca^{2+} transient was reported to be ameliorated by alfentanil, but this response may not be mediated by opioid receptors.[273] A study using transthoracic echocardiography demonstrated that continuous target-controlled infusion of remifentanil (target effect-site concentration 2 ng/mL, infusion rate 0.08-0.09 μg/kg/min) did not affect systolic and diastolic left ventricular function in young healthy subjects during spontaneous breathing.[274]

Cardiac Rhythm Conduction

Opioid-induced bradycardia is primarily mediated by the CNS. However, there have been reports on direct effects of opioids on cardiac pacemaker cells. Fentanyl may depress cardiac conduction by a mechanism mediated by direct membrane actions, as opposed to opioid receptor interactions.[275] During induction of anesthesia in patients undergoing coronary artery bypass graft surgery, the QT interval increased significantly after the injection of fentanyl.[276] However, pretreatment with fentanyl 2 μg/kg or remifentanil 1 μg/kg significantly attenuated QTc prolongation associated with laryngoscopy and tracheal intubation during propofol or sevoflurane induction.[277,278] Both sufentanil and alfentanil have been demonstrated to be devoid of electrophysiologic effects on the normal or accessory pathways in patients with Wolff-Parkinson-White syndrome.[279,280] Clinically, cardiac conduction disturbances attributable to opioids are rare, but they may be more likely to occur in the presence of Ca^{2+} channel or β-adrenergic blockers.

The overall effect of opioid anesthesia is antiarrhythmic. Naloxone, morphine, and levorphanol protected against arrhythmia induced by coronary artery occlusion in rats.[281] A direct effect on ionic currents in cardiac muscle was suggested as the mechanism of antiarrhythmic activity of opioids. It was also reported that opioid antagonists are more antiarrhythmogenic than agonists in rats.[282] Some of the electrophysiologic actions of opioids resemble those of class III antiarrhythmogenic drugs.

Myocardial Ischemia

Determining the effects and consequences of opioid action on myocardial ischemia is complex because results can depend on such factors as the species studied and experimental design. In an experimental model of myocardial ischemia in rabbits, fentanyl had antiarrhythmic and antiischemic action with central and peripheral opioid receptor involvement.[283] Opioids can mimic ischemic preconditioning. Opioid receptor stimulation results in a reduction in infarct size similar to that produced by ischemic preconditioning.[284] Although the preconditioning effect of opioids is mediated mainly by the cardiac κ- and δ-opioid receptors,[285] part of the protective effect of remifentanil may be produced by μ-agonist activity outside the heart.[286] Preconditioning with small doses of intrathecal morphine can provide comparable cardioprotection to myocardial ischemic preconditioning and preconditioning with intravenous morphine, and the effect seems to involve μ-, δ-, and κ-opioid receptors.[287] Late preconditioning, in which cardioprotective effects can be observed 24 hours after drug administration, was also produced by morphine-induced activation of the opioid receptor in rat hearts.[288]

It was found that remote preconditioning by brief ischemia of other distant organs, such as intestine, kidney, and limb, similarly provides cardioprotection that is as effective as classic ischemic preconditioning. The myocardial κ-opioid receptors were demonstrated to mediate cardioprotection by remote preconditioning.[289] Brief cycles of ischemia and reperfusion during the early phase of reperfusion protect the heart from infarction. This phenomenon, termed postconditioning, was shown to be induced by activation of the δ-opioid receptor in the heart.[290] Volatile anesthetics may also be capable of producing protection against ischemic injury when these drugs are administered solely on reperfusion. This anesthetic-induced postconditioning can be enhanced by morphine through the activation of phosphatidyl-3-kinase and opioid receptors.[291] It has been shown that brief exposure to exercise (1-3 days of moderate-intensity exercise) preconditions the heart against tissue injury and death resulting from myocardial ischemia–reperfusion. It was demonstrated that endogenous opioids produced in the heart mediate exercise-induced cardioprotection against ischemia–reperfusion injury through its action on the δ-opioid receptor in rats.[292] Stimulation of δ_1-opioid receptor also generates oxygen radicals through mitochondrial ATP-sensitive K^+ channels, with resulting attenuation of oxidant stress and cell death in cardiomyocytes.[293] Involvement of adenosine A1 receptor and protein kinase C in the cardioprotective effect of opioids was also suggested.[294,295] Whether the experimental results showing protective effects of opioid against myocardial ischemia will translate into reductions in morbidity and mortality in patients with coronary artery disease has yet to be established by clinical trials.[296] Clinically, high doses of opioids can maintain myocardial perfusion and the O_2 supply-demand ratio as well or better than can inhalation-based techniques.

Coronary Circulation

Opioids appear to have no significant effect on coronary vasomotion or myocardial metabolism, do not produce steal phenomena, nor diminish the ability of large coronary arterioles to respond to vasoactive agents.[297] Coronary conductance is regulated by arterial baroreflex control, and vasodilator response is induced by a rise in aortic pressure. This baroreflex control is enhanced by low plasma concentration of fentanyl (1-2 ng/mL), but appears to be depressed at increased concentrations of fentanyl.[298]

Circulatory Reflexes

In an experiment examining baroreceptor reflex responses induced by perfusion of the carotid sinus at predetermined levels, baroreceptor reflexes were well preserved by moderate doses of fentanyl while high doses of fentanyl depressed baroreceptor reflexes.[299] The oculocardiac reflex, which is caused by traction of extraocular muscles during strabismus surgery, was significantly augmented by fentanyl, sufentanil, and remifentanil.[300] Among pediatric patients undergoing strabismus surgery, anesthetized with propofol (12 mg/kg/h) and alfentanil (0.04 mg/kg/h), virtually all patients developed oculocardiac reflex and atrioventricular rhythm disorders were frequent.[301]

HISTAMINE RELEASE

It is well known that morphine causes histamine release and sympathoadrenal activation. Increases in plasma histamine after morphine cause dilation of terminal arterioles and direct positive cardiac chronotropic and inotropic actions. In patients pretreated with both H_1- and H_2-antagonists, the cardiovascular responses are significantly attenuated despite comparable increases in plasma histamine concentrations. Codeine and meperidine are examples of other opioids that can induce mast cell activation with the release of histamine, probably by a mechanism other than the μ-opioid receptors.[302] Unlike morphine or meperidine, the opioids fentanyl, alfentanil, sufentanil, and remifentanil do not produce increases in plasma histamine, subsequently hypotension is less frequent with their administration.

VASCULAR MECHANISMS

The pharmacologically defined opioid receptor subtype μ_3 is expressed in human endothelial cells and coupled to vasodilation via nitric oxide (NO) production. Although μ_3 is opiate alkaloid sensitive it is insensitive to opioid peptides including peptides previously shown to have affinities for the μ-opioid receptors. Morphine-induced vasodilation may be partially caused by activation of the μ_3 receptor.[303] Other pharmacologic studies evaluating alfentanil, fentanyl, and sufentanil in the dog also demonstrate direct peripheral vessel smooth muscle relaxation although exact mechanism(s) remains under study.[304,305] For example, measurement of forearm blood flow after infusion of sufentanil into the brachial artery indicated that sufentanil has a direct vasodilatory effect on human vascular tissue that is likely independent of a neurogenic or systemic mechanism.[306] A supraclinical dose of alfentanil attenuates the phenylephrine-induced contraction via an inhibitory effect on calcium influx by blocking the L-type calcium channels in the rat aortic vascular smooth muscle.[307] Remifentanil can cause transient instability in hemodynamic variables. However, this change may not be solely the result of autonomic or central nervous system inhibition or of centrally mediated vagal stimulation. A pharmacologic study using rat thoracic aortic rings indicated that remifentanil vasodilates by an endothelium-dependent mechanism, involving prostacyclin and NO released from the endothelium, and an endothelium-independent vasodilation probably mediated by the suppression of voltage-sensitive Ca^{2+} channels.[308] In patients with a total artificial heart in which cardiac output is preload-independent, remifentanil induces a dose-dependent and significant systemic vasodilation without significant effects on capacitance vessels.[309]

Opioids may affect the pulmonary vasculature as well as systemic circulation. It was shown that phenylephrine-induced contraction of canine pulmonary artery is primarily mediated by α_{1B}-adrenergic receptor activation, and is attenuated by fentanyl by binding to and directly inhibiting the α_{1B}-adrenergic receptor.[310] Pharmacologic studies in cats demonstrated that sufentanil and remifentanil have potent vasodepressor activity in the pulmonary vascular bed and these responses may be mediated by histamine and opioid receptor-sensitive pathway.[311,312]

OPIOIDS IN SHOCK

Opioids are often administered for patients requiring surgical intervention for the control of hemorrhage. An animal study demonstrated that pretreatment with morphine before inducing shock state decreases leukocyte adhesion and vascular permeability in the microcirculation of the mesenteric venule, suggesting the survival benefit for use of morphine during acute resuscitation.[313]

It has been shown that endogenous opioids contribute to the pathophysiology of hypovolemic shock through central and peripheral sympathetic inhibition and contributes to hypotension during severe hemorrhage. Liu et al. reported that the selective δ-opioid receptor antagonist (ICI 174,864) may be beneficial for the early management of traumatic hemorrhagic shock in rats, suggesting a pathophysiological role of the δ-opioid receptor in hemorrhagic shock.[314]

Endocrinologic Effects of Opioids

Opioids can induce a variety of endocrinological responses (Table 24.5).[315] In humans, opioids generally increase growth hormone, thyroid stimulating hormone, and prolactin, and decrease luteinizing hormone, testosterone, estradiol, and oxytocin. The effects of opioids on arginine vasopressin and ACTH are conflicting. The primary endocrine disorder that results from opioid misuse is hypogonadism, particularly in males.

Hormonal and metabolic responses to surgery are often extreme and are thought to contribute to operative mortality. Opioids are capable of reducing the stress response by modulating nociception at several levels of the neuraxis, as well as by influencing centrally mediated neuroendocrine responses. The main components of the neuroendocrine stress response are the corticotropin-releasing hormone brain centers (e.g., paraventricular hypothalamic nucleus) and the locus ceruleus-norepinephrine/autonomic nervous system. Increased levels of stress hormones are considered undesirable because they promote hemodynamic instability and intraoperative and postoperative metabolic catabolism. Opioids are potent inhibitors of the pituitary-adrenal axis.[316] Endogenous opioid peptides may serve as stress hormones themselves and not just as modulators of other hormones' secretion. This is suggested by the finding that β-endorphin and ACTH are derived from the same precursor preproopiomelanocortin and cosecreted during stress.

Morphine modifies hormonal responses to surgical trauma in a dose-related fashion through blockade of ACTH release, suppression of surgically induced increases in plasma cortisol, and attenuation of the pituitary-adrenal response to surgical stress. Morphine can increase some stress-responding hormones due to increases in plasma histamine release, adrenal medullary release mechanisms, and catecholamine release from sympathetic nerve endings.

TABLE 24.5 Summary of the Effects of Acute and Chronic Opioids on the Endocrine Systems of Animals and Humans

Fentanyl and its congeners are more effective than morphine in modifying hormonal responses to surgery. The efficacy of fentanyl in controlling the hormonal manifestations of the stress response can be dose-dependent. Fentanyl doses greater than or equal to 50 μg/kg can help to reduce the hyperglycemic response to cardiac surgery in pediatric patients to less than 200 mg/dL throughout operation.[317] In contrast, it has been demonstrated that neither fentanyl nor sufentanil alone can completely block sympathetic and hormonal stress responses and that perhaps no dose-response relationship exists for opioid-associated stress response control.[318] A randomized controlled trial showed that remifentanil (0.85 μg/kg/min), when compared with fentanyl (total doses of 15 and 28 μg/kg), blunts the hypertensive responses and cortisol excretion associated with cardiac surgery but is associated with more hypotension.[319]

STRESS REDUCTION AND OUTCOME

Anesthetic techniques or agents that minimize the stress response may reduce morbidity and mortality in a variety of circumstances. Anand and Hickey[320] evaluated the impact of sufentanil versus morphine-halothane anesthesia on hormonal and metabolic responses and morbidity and mortality in neonates undergoing cardiac surgery. Most strikingly, a difference in postoperative mortality was observed (0 of 30 given sufentanil versus 4 of 15 given halothane plus morphine). Mangano et al.[321] also reported that, after myocardial revascularization, patients receiving intense postoperative analgesia with sufentanil (1 μg/kg/h) experience a decrease in the incidence and severity of electrocardiographically documented ischemia compared with patients receiving intermittent IV morphine (2.2 ± 2.1 mg/h) for postoperative analgesia. It was also shown that large-dose opioids (remifentanil 0.85 μg/kg/min or fentanyl 28 μg/kg) were associated with a decreased rate of myocardial infarction after cardiac surgery.[319]

Many different hormonal changes induced by surgery have been described. However, the concomitant neural, cellular, immune, and biochemical changes have been less well defined, and little is understood or proven with regard to how modifying hormonal responses alters outcome.[322] Additional studies are necessary for complete elucidation of the relationship between control of the surgery-induced hormonal responses and outcome.

In summary, the mechanisms underlying the ability of opioids to provide perioperative cardiovascular stability include: a reduced sympathetic tone and enhanced parasympathetic activity often producing bradycardia; minimal changes in cardiac contractility; function generally as an antiarrhythmic; potentially function as cardioprotective agents to reduce the effect of ischemia by mimicking an endogenous opioid-peptide/preconditioning pathway; have no significant effect on the coronary circulation; produce modest vascular smooth muscle relaxation with the exception of a morphine-induced histaminergic mechanism; reduce the surgical stress response through the nervous system and adrenal-pituitary axis—depending on the opioid class.

OPIOID TOLERANCE

The precise mechanism(s) that drive opioid dependence and tolerance are not known, however they appear to encompass a range of factors including: genetic, molecular, cellular, physiologic, and functional. In the locus ceruleus, the major noradrenergic nucleus in the brain, long-term opioid exposure results in inhibition of adenylyl cyclase, reduced activity of protein kinase A, and upregulation of the cyclic AMP pathway.[323] Changes in μ-receptor density that occur prior to or during the development of tolerance do not appear to be essential for development of opioid tolerance.[324] Possible mechanisms involve protein kinase signal transduction cascades that link extracellular signals to cellular changes by regulating target gene expression. Central glucocorticoid receptors (GRs) have been implicated in the cellular mechanism of neuronal plasticity that has many cellular steps in common with the mechanism of opioid tolerance. It was shown that the development of tolerance to the antinociceptive effect of morphine was substantially attenuated when the GR antagonist was coadministered with morphine but the GR agonist dexamethasone facilitated the development of morphine tolerance, suggesting an important role of spinal GRs in the cellular mechanisms of morphine tolerance in rats.[325] Cholecystokinin and NMDA-NO system were also shown to be involved in development of acute tolerance to opioids,[326] which is also affected by spinal serotonin activity.[327] Neuroinflammation driven by chemokines may represent one of the major mechanisms underlying pathologic pain. A chemokine, CXCL1, was upregulated in both opioid-tolerant patients and rodents, and the onset and extent of opioid tolerance was affected by antagonizing intrathecal CXCL1/CXCR2 signaling.[328] A chemokine, CXCL12, was significantly upregulated in the cerebrospinal fluid of opioid-tolerant patients, and CXCL12 neutralizing antibody and antagonist for CXCR4, a receptor which interacts with CXCL12, attenuated morphine tolerance in rats.[329]

Morphine tolerance occurs more rapidly in younger rats than older rats and is unlikely to be the result of differences in drug metabolism or clearance, suggesting that aging may impact molecular processes involved in development of tolerance.[330] It has been suggested that activation of glial cells, including astrocytes and microglia, at the level of the spinal cord plays an important role in the development of opioid tolerance.[331,332] However, the mechanism for opioid-induced activation of glial cells is not completely understood.

Although the notion that opioid tolerance and dependence occur only after chronic administration has been widespread, it has now become recognized that tolerance can also develop rapidly after acute opioid exposure in animals and humans.[333,334] Intraoperative remifentanil infusion (0.3 μg/kg/min) in patients undergoing major abdominal surgery under desflurane anesthesia increased postoperative pain and morphine requirement compared with low-dose remifentanil (0.1 μg/kg/min), suggesting the development of acute remifentanil tolerance.[335] In contrast, there is a report that target-controlled infusion of alfentanil and remifentanil for postoperative analgesia does not lead to opioid tolerance.[336] In human volunteers, continuous infusion of remifentanil (0.08 μg/kg/min) for 3 hours did not decrease the pain threshold.[337] On the other hand, intraoperative use of 0.3 μg/kg/min remifentanil for approximately 3 hours did not induce acute tolerance, but the administration of 0.6 and 0.9 μg/kg/min remifentanil to young children resulted in acute tolerance for 24 hours after surgery revealed by increased use of postoperative fentanyl in an apparently dose-related manner.[338] Differences in these outcomes may reflect divergent methodologies and limited sample size and are an area of ongoing investigation.

Differential opioid tolerance, an important phenomenon in clinical opioid pharmacology, proposes that different targets of opioid drugs do not develop tolerance at the same rate and to the same degree.[339] In a study using rhesus monkeys, acute morphine administration predictably induced dose-dependent analgesia, and chronic morphine administration induced dose-dependent tolerance to the analgesic effect, while no tolerance development to the respiratory depressive effect could be demonstrated in the chronically opioid-treated animals (Fig. 24.14).[340] In humans, patients receiving chronic opioids for pain control, especially at high doses, most likely have developed opioid tolerance. However, there is little data to help predict the magnitude or clinical impact of an individual's loss of opioid-induced analgesia or potentially their resistance/vulnerability to the respiratory depressive effects of opioids. As discussed later, individuals chronically consuming opioids are dose dependently at increased risk for overdose and death.

MANAGEMENT OF OPIOID-DEPENDENT PATIENTS

A variety of problems should be taken into consideration for anesthetic management of opioid-dependent patients or patients suffering from opioid use disorder (OUD).[341] Complications in opioid-addicted patients include cardiopulmonary problems, renal problems, and anemia. Long-term morphine administration causes adrenal hypertrophy and impairs corticosteroid secretion. Viral and nonviral hepatitis, acquired immunodeficiency syndrome, osteomyelitis, muscle weakness, and neurologic complications may be found in patients suffering from OUD or poly substance use disorder. As it is common to underestimate and undertreat pain in opioid-dependent patients, it is important to identify the goals in their acute pain management (Box 24.3).[342] Anesthetic management for the opioid-dependent or patient with OUD should include adequate premedication with opioids, administration of supplemental intraoperative and postoperative opioids, and providing nonopioid analgesics and neural blockade. There is no ideal anesthetic agent or technique to employ in the patient with OUD or in the patient with an acute opioid overdose—with the possible exception of judicious use of an opioid antagonist as indicated. As mentioned previously, combined techniques utilizing regional anesthetic approaches, as well as concurrent use of low-dose ketamine and α2-agonists have been successful. Support of the circulatory system with fluids and monitoring of arterial blood gases and pulmonary function are essential.

Owing to the high risk of relapse, overdose, and death in individuals with OUD, medication-assisted treatment (MAT) in which opioids with different pharmacokinetic

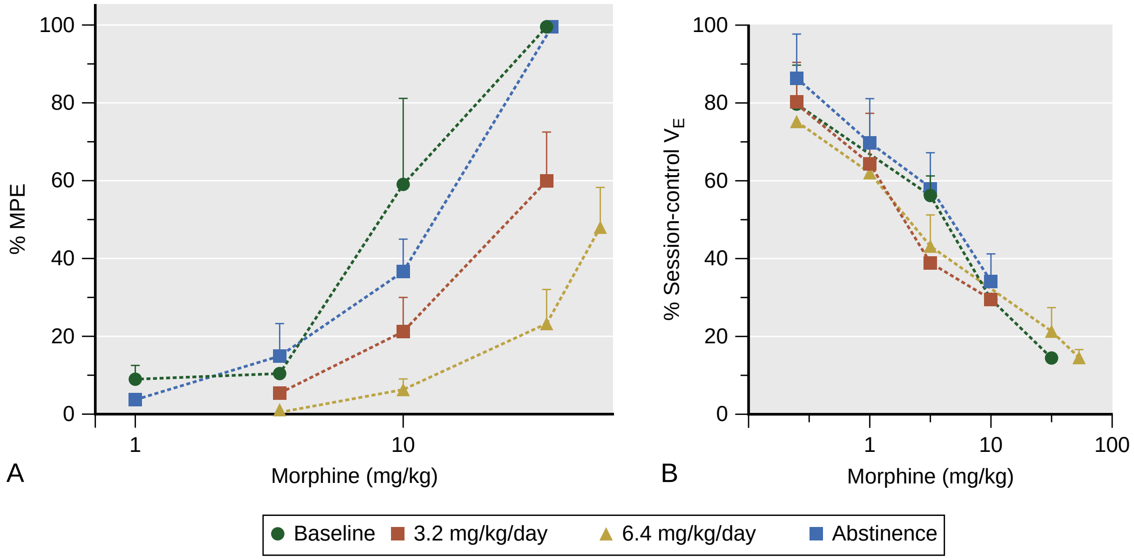

Fig. 24.14 The effects of chronic opioid administration on analgesia and respiratory response in rhesus monkeys. The animals were studied under baseline conditions, after receiving 3.2 or 6.4 mg/kg/day for 4 weeks, and after abstinence. After each treatment course, they were challenged with various doses of morphine, and analgesic and respiratory responses were assessed. Analgesic effects were assessed by tail withdrawal latency and shown as percentage of maximum possible effect *(MPE)*; respiratory depression was shown as decrease in minute ventilation *(V_E)*. The results show development of reversible tolerance to the analgesic effects of opioids (A), but no tolerance development to the respiratory depression (B). (From Paronis CA, Woods JH. Ventilation in morphine-maintained rhesus monkeys. ii: tolerance to the antinociceptive but not the ventilatory effects of morphine. *J Pharmacol Exp Ther*. 1997;282:355–362.)

BOX 24.3 **Goals of Acute Pain Management in Opioid-Dependent Patients**

1. Identification of the population of at-risk patients receiving long-term opioid therapy for various chronic pain situations (musculoskeletal disease, neuropathic conditions, sickle cell disease, HIV-related disease, palliative care), persons recovering in opioid maintenance programs
2. Prevention of withdrawal symptoms and complications
3. Symptomatic treatment of psychological affective disorders such as anxiety
4. Effective analgesic treatment in the acute phase
5. Rehabilitation to an acceptable and suitable maintenance opioid therapy

HIV, Human immunodeficiency virus.

and pharmacodynamic properties such as methadone or buprenorphine are commonly prescribed. Because of the injection-deterring potential of naloxone hydrochloride and a better safety profile compared with methadone, daily administration of combined buprenorphine and naloxone is becoming a first-line choice for MAT in a number of countries.[343] Other treatment approaches have emerged including rapid opioid detoxification with high-dose naloxone or naltrexone. For this treatment, general anesthesia is induced before the start of opioid antagonization and maintained for several hours to prevent perception of withdrawal symptoms by the patient.[344,345] Blockade of μ-opioid receptors by naloxone (total dose of 12.4 mg) in opioid-addicted patients induces sympathetic neural activation, including increase in plasma catecholamine concentration and cardiovascular stimulation, which can be managed in part by α_2-agonists.[346] Long-term opioid abstinence is not guaranteed, even with an ongoing program that includes MAT, given the neurobiology, societal factors involved in addiction, and potential for repeat exposure—often medically in the perioperative period.[347]

Renal and Urodynamic Effects of Opioids

Opioids can have significant effects on renal function. μ-receptor activation causes antidiuresis and decreases electrolyte excretion. κ-receptor stimulation predominantly produces diuresis with little change in electrolyte excretion. Indirect actions may involve inhibiting or altering the secretion of ADH and atrial natriuretic peptide. The absence of increases in plasma ADH, renin, and aldosterone indicate that fentanyl, sufentanil, alfentanil, and probably remifentanil most likely preserve or minimally alter renal function in humans. If renal function does change during opioid anesthesia and surgery, it is probably due to secondary changes in systemic and renal hemodynamics.

The mechanism by which opioids cause urinary retention is incompletely understood. Opioid effects on the lower urinary tract include disturbances of micturition characterized by urinary retention, especially after intrathecal opioid administration. Intrathecal administration of morphine and sufentanil caused dose-dependent suppression of detrusor contractility and decreased sensation of urge.[348] Mean times to recovery of normal lower urinary tract function were 5 and 8 hours after 10 or 30 μg sufentanil and 14 and 20 hours after 0.1 or 0.3 mg morphine, respectively. Not all opioid agonists behave similarly, and morphine appears to be particularly potent with regard to producing urodynamic problems. Malinovsky et al. compared urodynamic effects of intravenously administered morphine (10 mg), buprenorphine (0.3 mg), fentanyl (0.35 mg), and nalbuphine (20 mg).[349] It was shown that all of the opioids altered bladder sensations, but that detrusor contraction decreased only after administration of fentanyl and buprenorphine. Urinary retention induced by intravenous infusion of remifentanil, 0.15 μg/kg/min could be reversed by a single intravenous dose of methylnaltrexone 0.3 mg/kg or naloxone 0.01 mg/kg.[350] Reversal of urinary retention by methylnaltrexone indicates that peripheral mechanisms may play a role in opioid-induced bladder dysfunction.

A retrospective study for adult patients with chronic kidney disease undergoing orthopedic surgery estimated glomerular filtration rate during the postoperative period was significantly higher in the group in which remifentanil was used for anesthesia management than the group in which remifentanil was not used. This finding may suggest that anesthesia management using remifentanil may have a renal protective effect in adult patients with chronic kidney disease.[351]

Effects of Opioids on Digestive Organs

EFFECTS ON GASTROINTESTINAL TRACT

The adverse gastrointestinal effects of exogenous opioid treatment include nausea, vomiting, altered fluid dynamics, inhibited gastric emptying, inhibited intestinal coordinated propulsive activity, and increased transit time, all of which may contribute to postoperative ileus (Table 24.6).[352] Opioid-dependent mechanisms driving these effects are complex and those involving GI motility are believed to involve opioid receptors expressed throughout the myenteric plexus. Several opioid receptor types can be demonstrated on myenteric neurons, and both κ- and μ-receptor agonists regulate cholinergic transmission in the myenteric plexus. κ-Agonists appear to modulate acetylcholine release more potently than μ-agonists by inhibition of N-type voltage-sensitive Ca^{2+} channels via a pertussis toxin-sensitive G protein in guinea pig ileum.[353]

TABLE 24.6 Effects of Opioids on the Gastrointestinal Tract

Pharmacologic Action	Clinical Effect
Decreased gastric motility and emptying	Decreased appetite; increased gastroesophageal reflux
Decreased pyloric tone	Nausea and vomiting
Decreased enzymatic secretion	Delayed digestion; hard, dry stools
Inhibition of small and large bowel propulsion	Delayed absorption of medication; straining; incomplete evacuation; bloating; abdominal distension; constipation
Increased fluid and electrolyte absorption	Hard, dry stools
Increased nonpropulsive segmental contractions	Spasms; abdominal cramps; pain
Increased anal sphincter tone	Incomplete evacuation

From Viscusi ER, Gan TJ, Leslie JB, et al. Peripherally acting mu-opioid receptor antagonists and postoperative ileus: mechanisms of action and clinical applicability. *Anesth Analg*. 2009;108:1811–1822.

The effect of morphine on esophageal motility has been little explored. Morphine (80 μg/kg) increased the velocity but did not alter the amplitude or duration of primary peristalsis of the esophagus, and it decreased the duration and magnitude of swallow-induced lower esophageal sphincter relaxation.[354] Gastric emptying is delayed by opioids, via supraspinal (vagus nerve-mediated) and spinal, as well as peripheral, mechanisms. Intrathecal morphine (0.4 mg) significantly decreased the gastroduodenal propagation velocity and acetaminophen absorption, and intramuscular morphine (4 mg) gave additional effects.[355] Tramadol (1.25 mg/kg IV) has a measurable but smaller inhibitory effect on gastric emptying compared with codeine (1 mg/kg IV) or morphine (0.125 mg/kg IV).[356] Opioids administered epidurally as well as intrathecally reduce gastrointestinal motility.[355] It was reported that translocation of enteric microorganisms from the intestinal tract to extraintestinal sites is promoted by reduction of gut propulsion after morphine treatment in rats.[357] Propofol (0.3 mg/kg bolus and 1.0 mg/kg/h) abolished the decrease of gastric tone induced by morphine (0.1 mg/kg intravenously), but did not abolish morphine-induced delay of gastric emptying.[358]

Naloxone reverses opioid-induced delays in gastric emptying. Methylnaltrexone, a quaternary naloxone derivative that does not cross the blood-brain barrier, can attenuate morphine-induced delays in gastric emptying, suggesting that a peripheral mechanism is involved in the opioid effect on gastrointestinal tract.[359] Naloxone (0.7 mg/kg) significantly inhibited gastric emptying of saline and milk in rats.[360] This observation might suggest that opioids can affect the gastrointestinal tract by a mechanism independent from the opioid receptors. Intravenous, but not intramuscular, metoclopramide (10 mg) also can reverse morphine-induced delays in gastric emptying.[361]

Opioid effects on the intestine are complex. Transit time from mouth to ileum may not be significantly altered by morphine, because morphine enhances ileal propulsion before decreasing motility. Opioids increase tone and decrease propulsive activity in most of the intestine. Constipation is the frequent side effect in patients who are administered opioids. Naloxonazine attenuated the fentanyl-induced inhibition of gastrointestinal transit more potently than the inhibition induced by morphine or oxycodone. Naloxone methiodide suppressed the oxycodone-induced inhibition of gastrointestinal transit more potently than the inhibition induced by morphine.[362] Thus, μ-opioid receptor agonists induce the inhibition of gastrointestinal transit and drive constipation through different mechanisms.

BILIARY AND HEPATIC EFFECTS

Opioid agonists increase biliary duct pressure and sphincter of Oddi (choledochoduodenal sphincter) tone in a dose- and drug-dependent manner through opioid receptor-mediated mechanisms. However, the clinical consequences of opioid-induced biliary tract actions are usually minimal. Although traditional teaching dictates that morphine induces “spasm” in the sphincter of Oddi and should not be used in acute pancreatitis, no studies or evidence exist to indicate morphine is contraindicated for use in acute pancreatitis.[363] Increases in biliary pressure caused by opioids are, with the exception of meperidine, reversible with naloxone.

Oddi's sphincter manometry via choledochoscope demonstrated that the regular dose of morphine could increase common bile duct pressure, whereas pethidine had no effect on Oddi's sphincter motility and tramadol shows inhibited motility of the sphincter of Oddi.[364] Fragen et al. studied the effect of remifentanil (0.1 mg/kg/min) on the flow of dye from the gall bladder into the duodenum, and showed that remifentanil delays the drainage of dye from the gall bladder into the duodenum, but the delay is shorter than that reported after morphine or meperidine.[365]

Opioids produce minimal effects on liver function during anesthesia and surgery but can affect ischemia-reperfusion injury. Remifentanil pretreatment can attenuate liver injury induced by ischemia-reperfusion, which was shown to be mediated by inducible NO synthase expression and exhausting reactive oxygen species but does not involve opioid receptors.[366] Morphine administered either intravenously or intrathecally 10 minutes before 1 hour of ischemia protects against ischemia-reperfusion injury after 6 hours of reperfusion in both normal and cirrhotic rat liver by a mechanism involving the opioid receptor.[367] Remifentanil significantly attenuated increases in serum aminotransferase levels and the liver histological changes induced by ischemia-reperfusion injury of the liver in rats, by a mechanism possibly involving hepatic interleukin-18.[368] These reports might suggest the beneficial effects of opioids in anesthetic management of liver surgery.

NAUSEA AND VOMITING

Postoperative nausea and vomiting are serious problems which often embarrass anesthesiologists. Etiology, treatment, and prevention of PONV have been extensively investigated (Fig. 24.15).[369] Intraoperative use of opioids is a well-known risk factor for PONV .[370] Opioids stimulate the chemoreceptor trigger zone in the area postrema of the medulla possibly through δ-receptors, leading to nausea and vomiting. Alfentanil, compared with approximately equipotent doses of fentanyl and sufentanil, was found in one study to be associated with a lower incidence of PONV .[371]

The use of propofol in balanced or total IV anesthesia (TIVA) significantly reduces the incidence of opioid-induced nausea and vomiting. When opioids are employed, antiemetic prophylaxis should be considered, which includes drugs with anticholinergic activity, butyrophenones, dopamine antagonists, serotonin antagonists and acupressure. Ondansetron, a serotonin type 3 (5-HT_3) receptor antagonist, was proved to be effective for postoperative opioid-induced nausea and vomiting.[372] A meta-analysis concluded that prophylactic use of 5-HT_3 receptor antagonists significantly reduced the incidence of PONV and the need of rescue antiemetic therapy in parturients who received intrathecal morphine for cesarean delivery.[204] Nausea and vomiting after epidural morphine (3 mg) for postcesarean section analgesia could be prevented by dexamethasone (8 mg IV) as efficiently as droperidol (1.25 mg IV).[373] Cannabinoid receptor agonists have been demonstrated to be effective antiemetics in some clinical settings. Animal experiments have shown that the cannabinoid agonist suppresses opioid-induced retching and vomiting by activation of the cannabinoid CB1 receptor.[374] A continuous low-dose naloxone infusion (0.25 µg/kg/h) ameliorates some of the opioid-induced side effects, including nausea, vomiting, and pruritus, in many but not all patients without adversely affecting analgesia.[375] Transdermal scopolamine was shown to be effective for prophylactic use in parturients receiving intrathecal morphine while undergoing cesarean delivery but was associated with higher incidence of side effects such as dry mouth and blurry vision.[376]

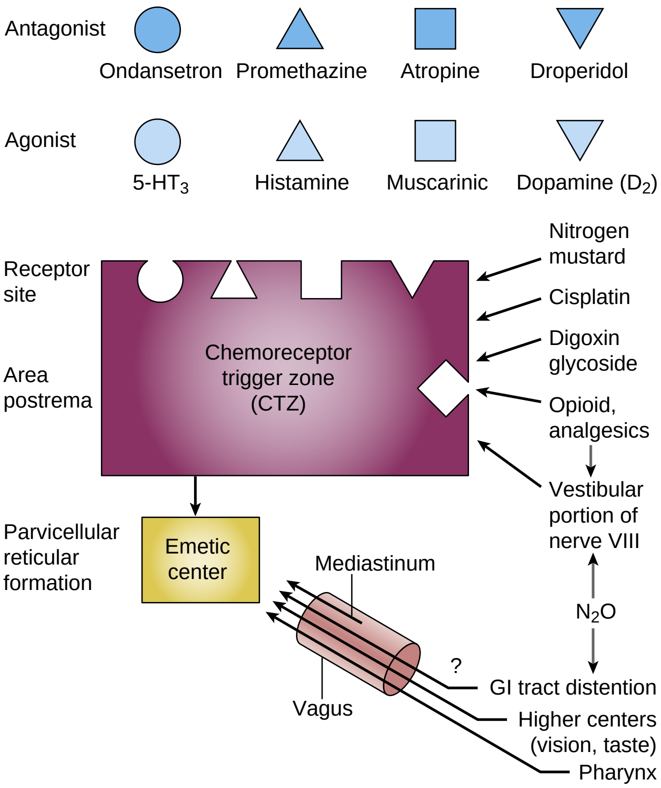

Fig. 24.15 The chemoreceptor trigger zone and the emetic center with the agonist and antagonist sites of action of various anesthetic-related agents and stimuli. *GI*, Gastrointestinal. (From Watcha MF, White PF. Postoperative nausea and vomiting: its etiology, treatment, and prevention. *Anesthesiology*. 1992;77:162–184.)

Taken together, the prevention and/or treatment of opioid-induced nausea and vomiting continues to be a clinical challenge. Strategies that include the administration of 5-HT_3 receptor antagonists and/or the steroid dexamethasone show efficacy in well controlled trials. However, such approaches require exposure to additional medications that, in themselves, may carry additional risks of side effects.

Other Opioid Effects

OBSTETRICS

The parenteral administration of opioids for oocyte retrieval and prior to delivery remains a commonly used method of analgesia.

Alfentanil and pethidine have been safely used as analgesics during the harvesting of human oocytes for subsequent *in vitro* fertilization.[377] Teratogenic actions of opioids, including fentanyl, sufentanil, and alfentanil, at least in animal models, appear to be minimal. Nociception due to uterine cervical distension could be suppressed by µ- and κ-agonists in rats,[378] but the analgesic effect of μ-agonist but not κ-agonist was reduced by estrogen.[379] Aortocaval compression and associated hypotension may be exacerbated by parenteral opioids, especially following morphine or meperidine. Fetal manifestations of maternal opioid administration include decreases in heart rate variability. Adverse neonatal effects can occur after either morphine or meperidine administration to mothers. Fetal acidosis increases opioid transfer from the mother. Attempts to minimize neonatal effects of opioids include restricting opioid administration to the first stage of labor. The short-acting opioid alfentanil administered before cesarean delivery attenuated the maternal stress response, but led to slightly reduced Apgar score.[380] In a randomized, double-blind, controlled study, it was shown that a single bolus of 1 μg/kg remifentanil administered to patients undergoing elective cesarean delivery effectively attenuated hemodynamic changes after induction and tracheal intubation, but remifentanil crosses the placenta and may cause mild neonatal depression.[381]

Because the fetus is capable of pain perception after the 26th week of gestation, adequate postoperative fetal pain management is essential after fetal surgery. It was shown that the sheep fetus absorbs sufentanil after intraamniotic instillation, and that significantly greater plasma concentrations were obtained in the fetal lamb as compared with the mother sheep.[382]

Morphine and meperidine have been found in the breast milk of mothers receiving intravenous opioid analgesia.[383,384] Although both fentanyl and morphine are concentrated in breast milk in milk-to-plasma ratios of 2 to 3:1, newborn exposure is reported to be insignificant. Newborns of mothers with OUD or taking prescription opioids can exhibit opioid withdrawal often referred to as neonatal abstinence syndrome (NAS) and require appropriate treatment and observation.[385,386]

ANAPHYLACTOID REACTIONS

True allergic reactions and systemic anaphylactoid reactions to opioids are rare. More commonly, local reactions caused by preservatives or histamine may occur. In 32% of heroin addicts dying suddenly after injection, the concentration of tryptase was elevated (>10 μg/L), but no correlation was found between the IgE levels and tryptase, supporting the hypothesis that mast cell degranulation was not mediated by allergic reaction.[387] This report suggests that heroin fatalities may be in part driven by anaphylactoid reaction.

OCULAR EFFECTS

The use of fentanyl, sufentanil, and alfentanil during induction of anesthesia can help to prevent increases in intraocular pressure. Fentanyl, alfentanil, and sufentanil doses as small as 2.5, 10, and 0.1 μg/kg, respectively, may be sufficient as long as appropriate anesthetic depth is achieved prior to tracheal intubation. Remifentanil (1 μg/kg) combined with propofol (2 mg/kg) or thiopental (5 mg/kg) was reported to be effective for prevention of intraocular pressure change after succinylcholine and tracheal intubation.[388,389]

IMMUNE EFFECTS

Opioids can affect immune function through adaptive immunity, innate immunity, and neuroendocrine system (Box 24.4).[390] The literature investigating the function of classical opioid receptors (μ, δ, and κ) present on immune cells suggest a complex relationship between clinically used opioids and immune function, including through indirect mechanisms. However, because the μ-opioid receptor knockout mice showed no immune modulatory effects after central administration of opioids, the central immune modulatory effect of opioids is mediated by μ-opioid receptors.[391]

It was shown that the maximal suppression of natural killer (NK) cell activity, proliferation of splenic T and B cells, and interferon-γ production are observed 0.5 to 1 hour after 15 mg/kg morphine injection in rats.[392] The time course

BOX 24.4 Opioid Effects on Immunity

Adaptive Immunity

↓ Splenic and thymic weight (rodents)
↓ T cell viability and proliferative response
↓ T-helper cell function
↓ CD4/CD8 population *in vivo*
↓ IL1β, IL-2, TNF-α, and IFN-γ (mouse splenocytes)
↓ Th1/Th2 ratio of T-helper cell population (PBMCs)
↓ NK cell activity
↓ Primary antibody response (B cells)
↓ B cells mitogenic response to bacterial LPS
↓ Macrophage activity
↓ TGF-β1 and IL-10 (antiinflammatory cytokines)
↑ T cell apoptosis (NF-κβ and AP-1/NFAT pathways)
Inhibition of CD3/28 mAb induced IL-2 transcripts

Innate Immunity

↓ Number of macrophages available to fight infections
↓ Leucocyte migration
↓ Peritoneal macrophages phagocytosis
↓ Respiratory burst activity and chemotaxis
Inhibition of Fc γ receptor mediated phagocytosis
↓ Superoxide production from neutrophils and macrophages
Alteration of IL-8 induced neutrophil chemotaxis
↓ Neutrophil cytokines involved in wound healing
↑ Apoptosis of macrophages impairing host defense barrier
↓ Leucocytes endothelial adhesion (intracellular adhesion molecules expression)

Neuroendocrine System

↑ Growth hormone, prolactin, and thyroid stimulating hormone secretion in humans
May affect the function of the HPA axis (ACTH and CRH) with risk of adrenal insufficiency
↓ Sex hormones [LH and testosterone (hypogonadism)], oxytocin, and estradiol

ACTH, Adrenocorticotropic hormone; *AP-1*, activator protein 1; *CRH*, corticotropin releasing hormone; *Fc*, fragment crystallizable region; *HPA*, hypothalamic pituitary adrenal axis; *IL*, interleukin; *IFN-γ*, interferon-gamma; *LH*, luteinizing hormone; *LPS*, lipopolysaccharides; *NF-κβ*, nuclear factor kappa beta; *NFAT*, nuclear factor of activated T-cells; *NK*, natural killer; *PBMC*, peripheral blood mononuclear cell; *TGF-β*, transforming growth factor beta; *TNF-α*, tumor necrosis factor-alpha.

was nearly concordant with the antinociceptive effect of morphine. Postoperative administration of morphine (10 mg IM) did not significantly affect the NK cell activity, while tramadol (100 mg IM) enhanced NK cell activity.[393] It was reported that intravenously administered fentanyl causes a rapid increase in NK cell cytotoxicity, which was coincident with an increase in the percentage of $CD16^+$ and $CD8^+$ cells in peripheral blood.[394] Compared with fentanyl (1000 μg), administration of morphine (40 mg) as part of balanced anesthetic technique suppressed several components of the inflammatory response (IL-6, CD11b, CD18, postoperative hyperthermia) to cardiac surgery and cardiopulmonary bypass.[395]

As a potential mechanism for the immunosuppressive effects of morphine, it was demonstrated that NF-κβ activation induced by an inflammatory stimulus was inhibited by morphine-induced activation of μ_3-opioid receptors in a NO-dependent manner.[396] Several investigators have independently reported direct effects of morphine on apoptosis in cultured human peripheral blood lymphocytes, which may result in compromising immune functions.[397] However, there is also a report that morphine has no effect on apoptosis-related molecules and does not promote apoptosis of human peripheral blood lymphocytes.[398]

With respect to the effects of opioids on neutrophils, it was reported that remifentanil, but not sufentanil, alfentanil, or fentanyl, could attenuate activation of human neutrophils exposed to lipopolysaccharides, and decreased activation of intracellular signaling pathways, including p38 and ERK1/2, and expression of proinflammatory cytokines, including TNF-α, IL-6, and IL-8, through a mechanism involving the κ-opioid receptor.[399] It was also reported that remifentanil attenuates lipopolysaccharide-induced acute lung injury by inhibition of proinflammatory cytokine production by downregulating the NF-κβ pathway, suggesting a beneficial effect of remifentanil in acute lung injury or acute respiratory distress syndrome in sepsis.[400]

A prospective study for adult patients who underwent elective colorectal surgery demonstrated that the number of patients who developed surgical site infection was higher after remifentanil-based anesthesia (11.6%) compared with fentanyl-based anesthesia (3.4%).[401] A possible reason for this finding may be opioid-induced immunosuppression or opioid withdrawal-induced immunosuppression.

CANCER PROGRESSION

Epidemiological studies have suggested that patients who receive general anesthesia with opioids have a greater rate of cancer recurrence than patients who receive local or regional anesthetics,[402] although there is no direct evidence to support altering anesthetic technique in cancer patients. Opioids may directly stimulate proliferation and invasion of tumor cells and inhibit apoptosis of tumor cells, or indirectly affect cancer recurrence by immunosuppression.[403] Overexpression of the μ-opioid receptor in human non-small cell lung cancer was suggested to promote tumor growth and progression.[404] Furthermore, it was reported that women with A118G genotype of the μ-opioid receptor have decreased breast cancer-specific mortality, suggesting that opioid pathways may be involved in tumor growth.[405] Drawing from preclinical studies using animals or cultured cells opioids may promote tumor growth and metastasis through multiple mechanisms, whereas it is also reported that opioids can direct various anticarcinogenic pathways (Fig. 24.16).[406] Preclinical data have also suggested that μ-opioid receptor inhibition can reverse the adverse effect of μ-opioid receptor signaling on cancer progression, when a combination of methylnaltrexone, which blocks peripheral but not central μ-opioid receptor, and chemotherapy is tested.[407]

One of the mechanisms involved in the effects of opioids on cancer prognosis is their effects on angiogenesis. Morphine can stimulate angiogenesis by a variety of mechanisms involving NO, MAPK, VEGF, and Rho/Rho kinase.[408] Blebea et al. reported that activation of opioid receptors inhibited angiogenesis, via endogenous opioid ligands.[409] Although both pro- and anti-angiogenic actions of opioids have been reported, it is generally believed that the proangiogenic (or neo-vasculogenic) effects predominate.

The opioid growth factor receptor (OGFR) is localized in both the nucleus and the cytoplasm and functions as a receptor for OGF, also known as methionine-enkephalin. OGFR is distinguished from classic opioid receptors (μ, δ, and κ) as not having any role in analgesia but functions as a negative regulator of cell proliferation. Morphine can also interact with OGFR expressed in lung cancer tissues and cell lines and may suppress lung cancer progression.[410]

WOUND HEALING

Topical application of opioids has been explored as a strategy for reducing pain associated with cutaneous wounds. In addition to its analgesic functions, the peripheral opioid receptor system affects skin homeostasis by influencing cell differentiation, migration, and adhesion. Activation of peripheral opioid receptors on primary afferent neurons reduces the excitability of these neurons and suppresses the antidromic release of substance P and calcitonin gene-related peptide, which play an essential role in wound repair. It was shown that topical morphine application significantly reduced the number of myofibroblasts and macrophages in the closing wound.[411] These findings might limit the topical application of opioids as an analgesic therapeutic strategy in the treatment of painful cutaneous wounds. In contrast, it was shown that activation of the δ-opioid receptors destabilizes intercellular adhesion and promotes the migratory keratinocyte phenotype, which is required for fast wound closure.[412] If these divergent findings can be resolved in favor of wound healing and enhanced localized analgesia, there is great potential for opioid applications in wound healing. Most clinical studies have not focused on opioid effects on the wound healing process but substantial analgesic effects without delaying wound closure were found. Larger clinical trials are required to examine whether opioids interfere with wound healing by inhibition of proinflammatory cytokine release or by development of hypertrophic scars, as shown in animal studies.[413]

analyze and model pharmacologic data which separates drug response into pharmacokinetic and pharmacodynamic components. Pharmacokinetic parameters govern the relationship between opioid dose and the opioid concentrations in the blood (or other body fluids). Pharmacodynamic parameters describe the relationship between opioid concentration in blood (or other fluids) and opioid effect.

Computer simulation techniques predict "context-sensitive half–times," the time necessary to achieve a 50% decrease in drug concentration after termination of a variable-length continuous infusion to a steady-state drug level (see Chapter 26). Such simulations are intended to provide more clinically relevant meaning to pharmacokinetic parameters. The context-sensitive half-time and computer simulations have helped clinicians to select opioids in a more rational fashion. After 1-hour continuous infusion, the context-sensitive half-time of fentanyl is nearly six times that of alfentanil or sufentanil. Remifentanil's context-sensitive half-time is independent of infusion duration.

PHYSICOCHEMICAL PROPERTIES

Opioids are weak bases. When dissolved in solution, they are dissociated into protonated and free-base fractions, with the relative proportions depending on the pH and pKa. The free-base fraction is more lipid-soluble than the protonated fraction. High lipid solubility facilitates opioid transport into the biophase or site of action. Therefore, highly lipid-soluble opioids have a more rapid onset of action. However, because the opioid receptor recognizes an opioid molecule in the protonated form, the intensity of opioid effects is closely related to the ionized concentration of drug in the biophase.

All opioids are to some extent bound to plasma proteins, including albumin and α_1-acid glycoprotein. It is only the un-ionized, unbound fraction that constitutes the diffusible fraction and provides the concentration gradient that promotes diffusion of opioid from the blood to the tissue of interest. Thus, the speed of onset of opioid effect is affected by both the lipid solubility and the protein binding.

PHARMACOKINETIC FEATURES OF INDIVIDUAL DRUGS

Representative pharmacokinetic parameters for the opioids commonly used in anesthesia are displayed in Table 24.7.

Morphine

Morphine pharmacokinetics is notably different from that of the fentanyl congeners. This difference is in large part due to morphine's comparatively low lipid solubility. There is relatively little transient first-pass uptake

TABLE 24.7 Physicochemical and Pharmacokinetic Data of Commonly Used Opioid Agonists

	Morphine	Fentanyl	Sufentanil	Alfentanil	Remifentanil

of morphine by the lung. The pKa of morphine (8.0) is greater than physiologic pH, and thus after intravenous injection only a small fraction (10%-20%) of morphine is un-ionized. Penetration of morphine into and out of the brain is presumably slower compared with that of other opioids. Approximately 20% to 40% of morphine is bound to plasma proteins, mostly albumin.

Morphine is principally metabolized by conjugation in the liver, but the kidney plays a key role in the extrahepatic metabolism of morphine. M3G is the major metabolite of morphine, but does not bind to opioid receptors and possesses little or no analgesic activity. M3G may actually antagonize morphine, and this effect may contribute to both variability in response and resistance to morphine analgesic therapy. M3G was reported to produce seizures in animals and cause allodynia in children.[414] M6G accounts for nearly 10% of morphine metabolite and is a more potent μ-receptor agonist than morphine with a similar duration of action. It was reported that M6G contributes substantially to morphine's analgesic effects even in patients with normal renal function.[415] A recent study reported that based on area under the concentration–time curve there was a major contribution of M6G to the overall analgesic effect; the mean contributions being estimated as 96.6%, 85.6%, 85.4%, and 91.3% after oral, subcutaneous, intravenous, and rectal administration of morphine, respectively.[416] In patients with renal insufficiency, 97.6% of the analgesic effect is caused by M6G when morphine is given orally. Especially in patients with renal dysfunction, the accumulation of M6G can lead to an increased incidence of adverse effects, including respiratory depression. Except for renal function, M6G accumulation was shown to be affected by transmembrane transporters inhibited by probenecid.[417] M6G can induce respiratory depression similarly as morphine, but the site of action in the ventilatory control system might be different between M6G and morphine.[418] It was suggested that SNP at the μ-opioid receptor affects the susceptibility to M6G-related opioid toxicity.[419] Because the hepatic extraction ratio of morphine is high, the bioavailability of orally administered morphine is significantly lower (20%-30%) than after intramuscular or subcutaneous injection. It appears that M6G is in fact the primary active compound when morphine is administered orally (Fig. 24.17).[420] In contrast to the reports suggesting the high potency of M6G, there have been reports showing that short-term intravenous administration of M6G does not provide effective analgesia.[421]

Fentanyl

A three-compartment model is typically used to describe plasma fentanyl concentration decay. The lungs exert a significant first-pass effect and transiently take up approximately 75% of an injected dose of fentanyl. Approximately 80% of fentanyl is bound to plasma proteins, and significant amounts (40%) are taken up by red blood cells. Fentanyl is relatively long acting, in large part because of this widespread distribution in body tissues.

Fentanyl is primarily metabolized in the liver by *N*-dealkylation and hydroxylation. Metabolites begin to appear in the plasma as early as 1.5 minutes after injection. Norfentanyl, the primary metabolite, is detectable in the urine for up to 48 hours after intravenous fentanyl in humans.

Alfentanil

Following IV injection, alfentanil plasma concentrations are described by either two-compartment or three-compartment model. Alfentanil is bound to plasma proteins (mostly glycoproteins) in higher proportions (92%) than fentanyl. At physiologic pH, it is mostly (90%) un-ionized because of its relatively low pKa (6.5). Thus, despite more intense protein binding, the diffusible fraction of alfentanil is higher than fentanyl. This explains, in part, its short latency to peak effect after intravenous injection.

The main metabolic pathways of alfentanil are similar to those of sufentanil and include oxidative *N*-dealkylation

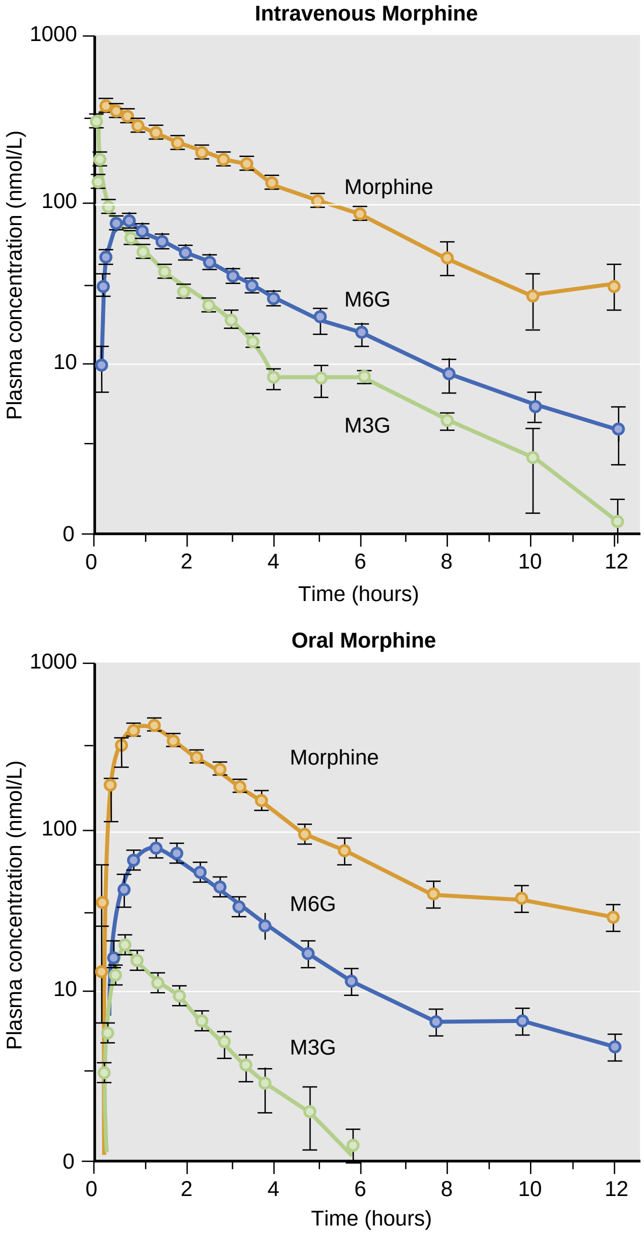

Fig. 24.17 Mean plasma concentrations (± standard error of means) of morphine, morphine-6-glucuronide *(M6G)*, and morphine-3-glucuronide *(M3G)* after intravenous and oral administration of morphine. (From Osborne R, Joel S, Trew D, et al. Morphine and metabolite behavior after different routes of morphine administration: demonstration of the importance of the active metabolite morphine-6-glucuronide. *Clin Pharmacol Ther*. 1990;47:12–19.)

and *O*-demethylation, aromatic hydroxylation, and ether glucuronide formation. The degradation products of alfentanil have little, if any, opioid activity. Human alfentanil metabolism may be predominantly, if not exclusively, by cytochrome P-450 3A3/4 (CYP3A3/4).[422] This enzyme is known to display at least 8-fold difference in activity in humans. Alfentanil is also metabolized by human liver microsomal CYP3A5, which shows more than 20-fold pharmacogenetic variability in expression level leading to significant differences in human liver alfentanil metabolism.[423] In vitro study demonstrated that propofol in clinically relevant concentrations interferes with oxidative metabolic degradation of alfentanil and sufentanil in the microsomal fraction of pig and human liver.[424]

Sufentanil

The pharmacokinetic property of sufentanil is adequately described by a three-compartment model. After intravenous injection, first-pass pulmonary extraction, retention, and release are similar to those of fentanyl.[425] The pKa of sufentanil at physiologic pH is the same as that of morphine (8.0), and, therefore, only a small amount (20%) exists in the un-ionized form. Sufentanil is twice as lipid-soluble as fentanyl and is highly bound (93%) to plasma proteins including α_1-acid glycoprotein.

The major metabolic pathways of sufentanil include *N*-dealkylation, oxidative *O*-demethylation, and aromatic hydroxylation. Major metabolites include *N*-phenylpropanamide.

Remifentanil

Although chemically related to the fentanyl congeners, remifentanil is structurally unique because of its ester linkages. Remifentanil's ester structure renders it susceptible to hydrolysis by blood- and tissue-nonspecific esterases, resulting in rapid metabolism and rapid reduction of blood concentration after an infusion has stopped (Fig. 24.18).[426] Remifentanil thus constitutes the first ultrashort-acting opioid for use as a supplement to general anesthesia.

Pharmacokinetic properties of remifentanil are best described by a three-compartment model. Its clearance is several times greater than normal hepatic blood flow, consistent with widespread extrahepatic metabolism. But, remifentanil is not significantly metabolized or sequestered in the lungs.[427] It is a weak base with a pKa of 7.07. It is highly lipid-soluble with an octanol/water partition coefficient of 19.9 at pH 7.4. Remifentanil is highly bound (= 70%) to plasma proteins (mostly α_1-acid glycoprotein). The remifentanil free base is formulated with glycine. Because glycine has been shown to act as an inhibitory neurotransmitter that causes a reversible motor weakness when injected intrathecally in rodents, remifentanil is not approved for spinal or epidural use.[428]

The primary metabolic pathway of remifentanil is de-esterification to form a carboxylic acid metabolite, GR-90291 (Fig. 24.19),[429] which is 0.003 to 0.001 times as potent as remifentanil. The low *in vivo* potency of GR90291 can be explained by its low affinity to the μ-receptor in combination with a poor brain penetration.[430] Excretion of GR-90291 is dependent on renal clearance mechanisms. Evidence from dogs suggests that the remifentanil metabolites are, for practical purposes, completely inactive, even in the face of renal failure. Its pharmacokinetics is not appreciably influenced by renal or hepatic failure. In blood, remifentanil is metabolized primarily by enzymes within erythrocytes. Remifentanil is not a good substrate for pseudocholinesterase and, therefore, is not influenced by pseudocholinesterase deficiency.[431]

SURROGATE MEASURES OF OPIOID POTENCY

Because a high-resolution measure of analgesia is not available, opioid potencies are usually estimated by some surrogate measures. Reduction of the MAC required to produce lack of movement to skin incision has been a

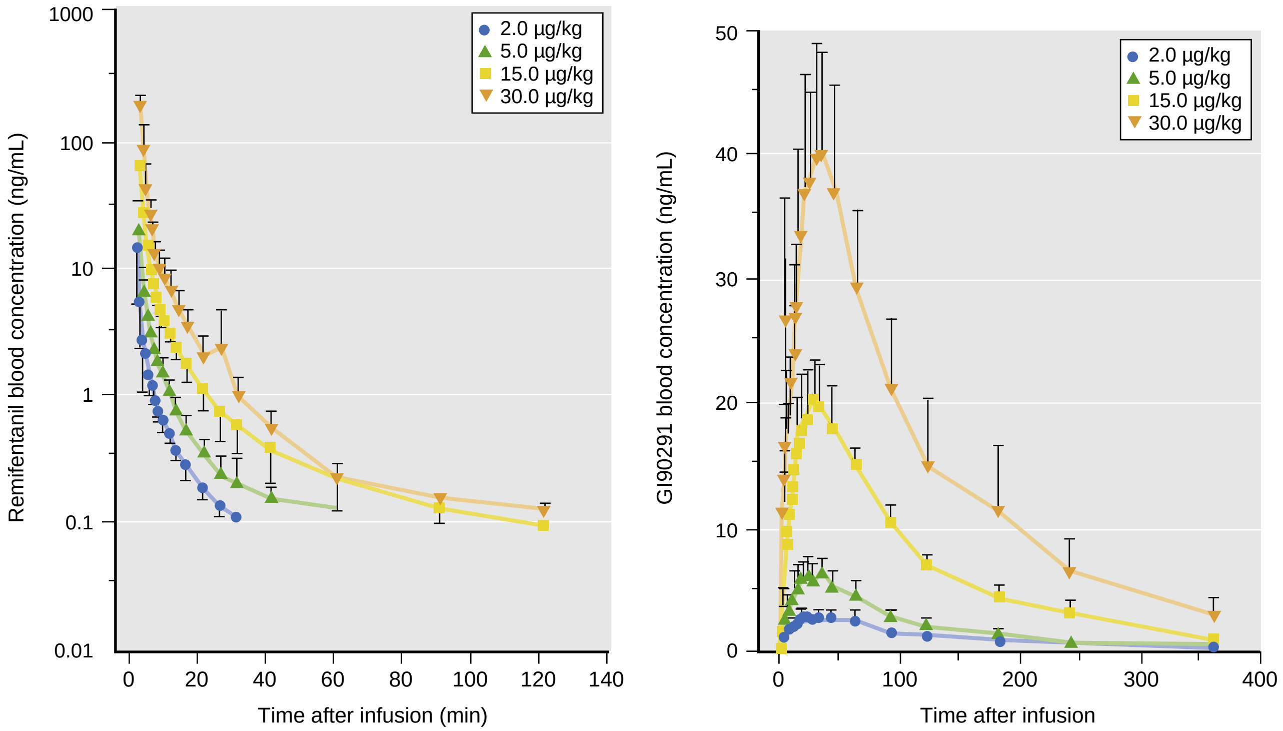

Fig. 24.18 Mean (± standard deviation) blood concentration-time curves of remifentanil and its metabolite GI90291 after a 1-minute transfusion of remifentanil of 2, 5, 15, and 30 μg/kg (*n* = 6 for each dose). (From Westmoreland CL, Hoke JF, Sebel PS, et al. Pharmacokinetics of remifentanil (GI87084B) and its major metabolite (GI90291) in patients undergoing elective inpatient surgery. *Anesthesiology*. 1993;79:893–903.)

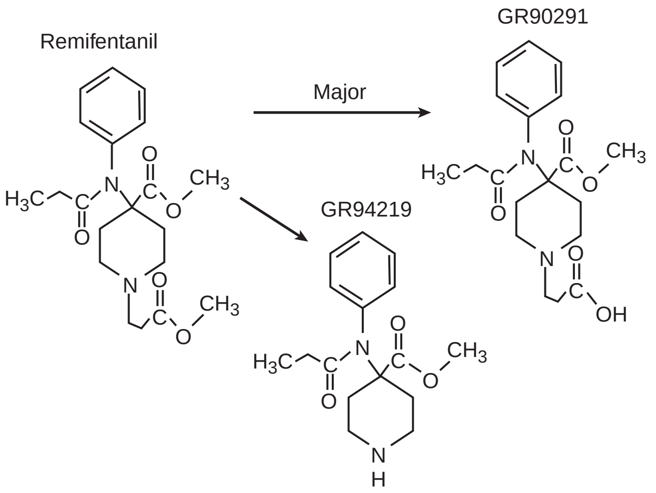

Fig. 24.19 Metabolic pathway of remifentanil. Deesterification by nonspecific plasma and tissue esterases to form a carboxylic acid metabolite *(GR90291)* that has only 1/300 to 1/1000 the potency of the parent compound is the primary metabolic pathway. *N*-dealkylation of remifentanil to *GR94219* is a minor metabolic pathway. (From Egan TD, Lemmens HJ, Fiset P, et al. The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. *Anesthesiology*. 1993;79:881–892.)

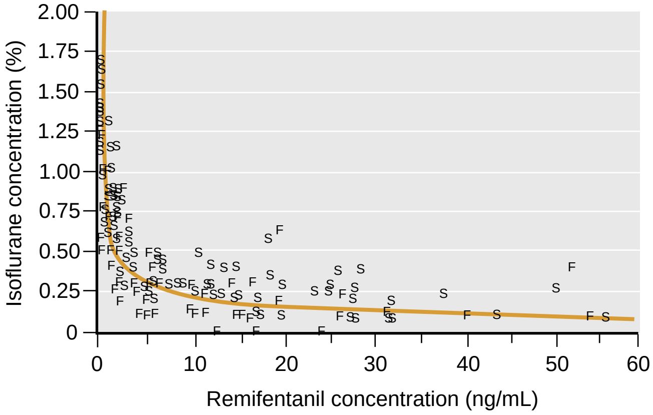

Fig. 24.20 The reduction in isoflurane concentration to prevent movement at skin incision in 50% of patients by increasing measured remifentanil whole blood concentrations. *F* represents a patient who moved and *S* represents a patient who did not move. The solid line is the logistic regression solution for a 40-year-old patient. (From Lang E, Kapila A, Shlugman D, et al. Reduction of isoflurane minimal alveolar concentration by remifentanil. *Anesthesiology*. 1995;85:721–728.)

frequently utilized surrogate measure in the estimation of opioid potency (Fig. 24.20).[125] However, MAC is not useful as a surrogate measure of opioid potencies outside the operation rooms.

To guide the administration of opioids in anesthetized patients, indirect parameters that reflect the patient's physiologic reaction to nociception like sweating, movement, heart rate, and blood pressure should be monitored. However, the low specificity of these signs can cause underdosage or overdosage of intraoperative analgesia. The Analgesia Nociception Index (ANI), derived from an electrocardiogram trace, has been proposed as a noninvasive guide to analgesia.[432] The ANI monitor calculates heart rate variation with respiration, a response mediated primarily by changes in the parasympathetic nervous system stimulation to the sinoatrial node of the heart. Patients receiving

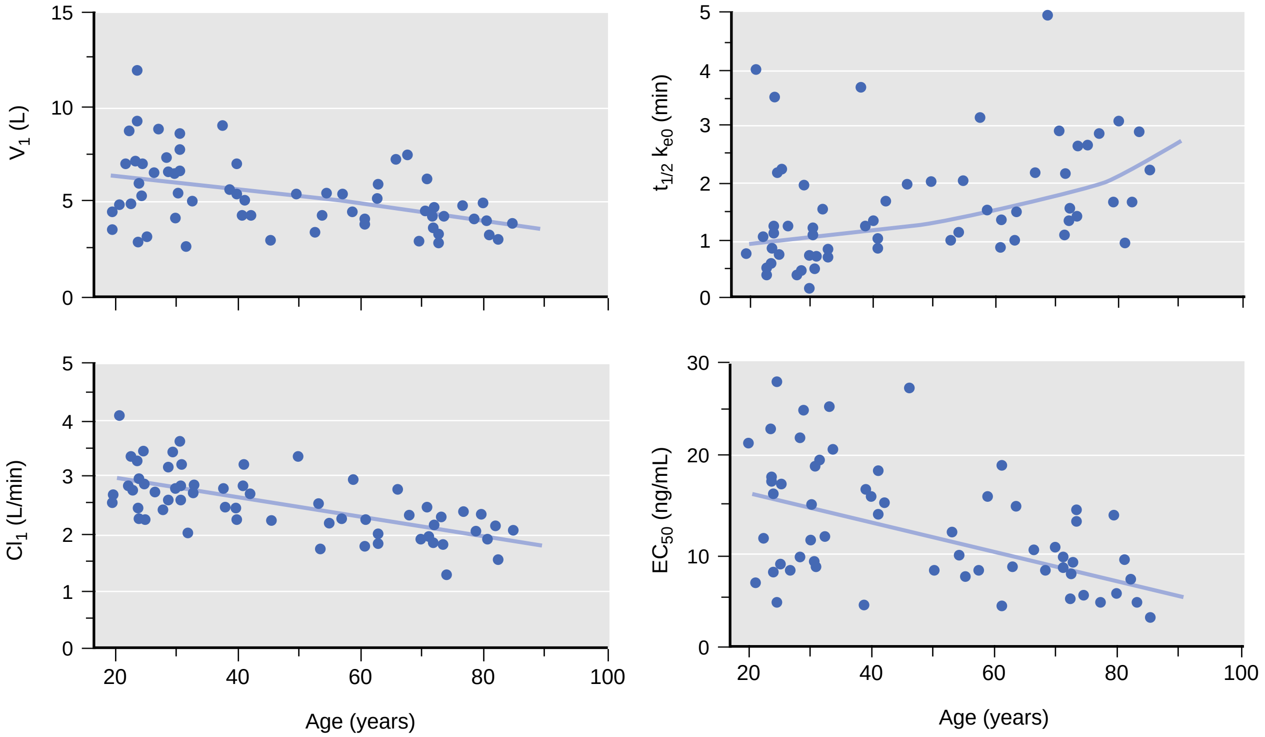

Fig. 24.21 Relationship between pharmacokinetic and pharmacodynamic parameters and age for remifentanil. Volume of distribution *(V_1)* and clearance *(Cl_1)* are estimated using a three-compartment model. $t_{1/2}k_{e0}$ is a half-life corresponding to k_{e0}, a first-order rate constant for elimination of drug from the effect compartment. (From Minto CF, Schnider TW, Shafer SL. Pharmacokinetics and pharmacodynamics of remifentanil. II. Model application. *Anesthesiology*. 1997;86:24–33.)

intraoperative ANI-guided fentanyl administration during sevoflurane anesthesia for lumbar discectomy and laminectomy demonstrated decreased pain in the recovery room, likely as a result of more objective intraoperative fentanyl administration.[433]

The EEG has been another widely utilized surrogate measure in estimating opioid potency. The EEG is advantageous, because it is noninvasive and can be used as an effect measure when an experimental subject is unconscious or apneic. When processed by Fourier spectral analysis, the raw EEG changes translate into a significant decrease in the value of the spectral edge, a parameter that quantitates the frequency below which a given percentage (usually 95%) of the power in the EEG signal is found. Although the clinical meaning of the EEG changes produced by opioids is unclear, the opioid potencies estimated using the EEG as a surrogate measure appear to be clinically reliable because they relate to clinically determined potencies in a proportional, reproducible fashion. However, because the surrogate measures do not always assess the drug effect of clinical interest (analgesia), estimations of potency based on surrogate measures must be interpreted with caution.

FACTORS AFFECTING PHARMACOKINETICS AND PHARMACODYNAMICS OF OPIOIDS

Age

Pharmacokinetics and pharmacodynamics of opioids can be influenced by age. It is clear that neonates exhibit a reduced rate of elimination of essentially all opioids.[434] This is presumably due to immature metabolic mechanisms, including the cytochrome P-450 system. The prolonged elimination of opioids observed in the neonatal period quickly normalizes toward adult values within the first year of life.[434]

Intraoperative requirements of opioids are different between adults and children. The infusion rate of remifentanil to block somatic and autonomic response to skin incision was almost 2-fold higher in children (2-11 years) than adults (20-60 years).[435,436] With advanced age, although pharmacokinetic changes may play a minor role, pharmacodynamic differences are primarily responsible for the decreased dose requirement in the elderly. Age was inversely correlated with central volume of distribution, clearance, and potency of remifentanil (Fig. 24.21).[437] These combined pharmacokinetic and pharmacodynamic changes mandate a reduction in remifentanil dosage by at least 50% or more in the elderly.

Body Weight

Many opioid pharmacokinetic parameters, especially clearance, appear to be more closely related to lean body mass. Total body weight-based dosing in an obese patient results in much higher remifentanil effect-site concentrations than does lean body mass-based dosing.[438] In contrast, for lean patients, the concentrations that result from total body weight-based dosing are not much greater than those based on body mass (Fig. 24.22). Clinically, context-sensitive half-times are not significantly different between obese and lean subjects (Fig. 24.23). There is mounting evidence to suggest that lean body mass is a better predictor of metabolic capacity than total body weight. Ideal body weight, a parameter closely related to lean body mass and one that

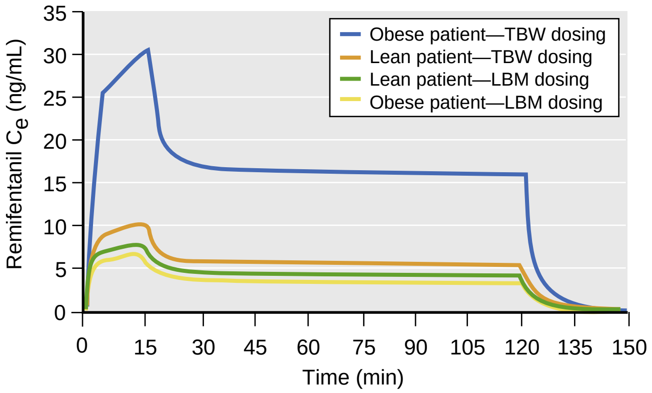

Fig. 24.22 A computer simulation of the time course of remifentanil concentration change, when the dosage regimen is calculated based on lean body mass *(LBM)* or total body weight *(TBW)* for both obese and lean patients. Note that TBW-based dosing in an obese patient results in dramatically higher concentrations. (From Egan TD, Huizinga B, Gupta SK, et al. Remifentanil pharmacokinetics in obese versus lean patients. *Anesthesiology*. 1998;89:562–573.)

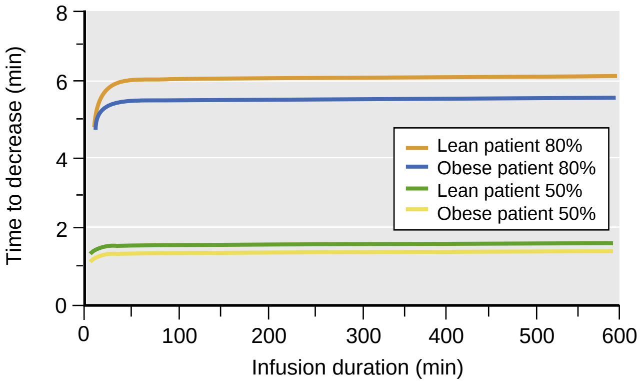

Fig. 24.23 A computer simulation of the context-sensitive half-times (50% decrement times) and 80% decrement times of remifentanil in obese vs. lean subjects. In clinical terms, the curves are not grossly different in obese and lean subjects. (From Egan TD, Huizinga B, Gupta SK, et al. Remifentanil pharmacokinetics in obese versus lean patients. *Anesthesiology*. 1998;89:562–573.)

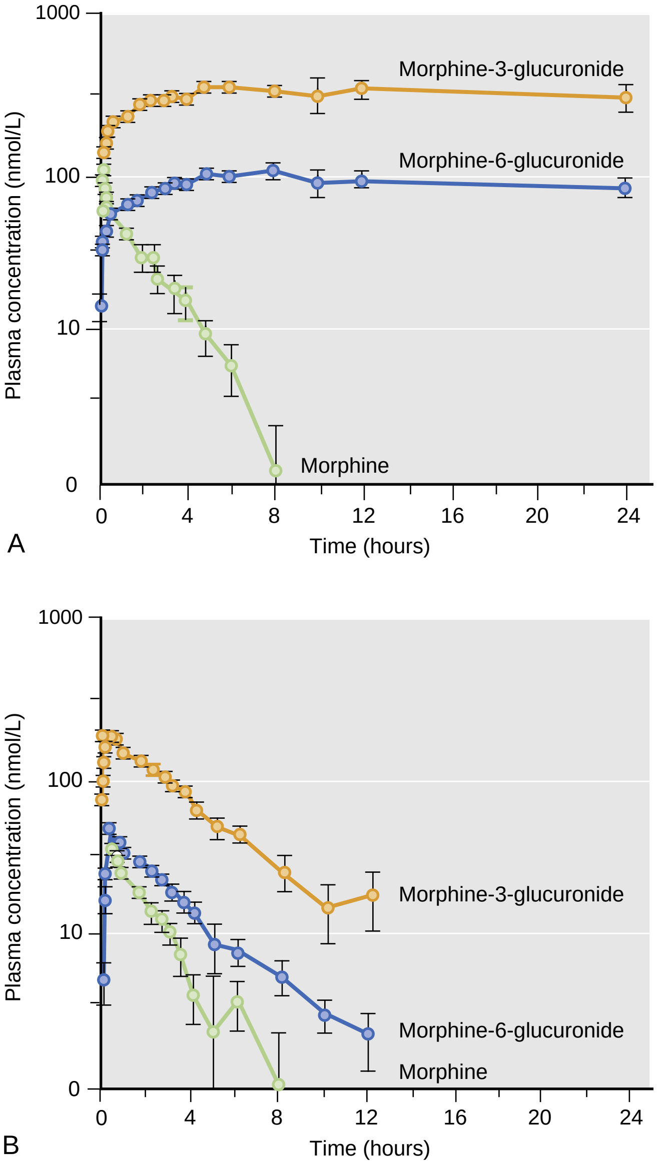

Fig. 24.24 Effect of renal failure on pharmacokinetics of morphine. The graphs show the time-dependent change of the serum concentration of morphine and its metabolite in patients of renal failure (A) and in patients with normal renal function (B) who received 0.1 mg/kg morphine intravenously. (From Osborne R, Joel S, Grebenik K, et al. The pharmacokinetics of morphine and morphine glucuronides in kidney failure. *Clin Pharmacol Ther*. 1993;54:158–167.)

is perhaps more easily estimated by the clinician, is probably an acceptable alternative of lean body mass. Because obesity and obesity-associated disease have increased and continue to do so, obese patients will frequently present for anesthesia and operations. Understanding the influence of obesity on the disposition of opioids is an important question in contemporary anesthesia practice. In response, new pharmacokinetic models incorporating the influence of body mass have been recently reported.[439,440]

Renal Failure

Renal failure has implications of major clinical importance with respect to morphine, hydromorphone, and meperidine. For the fentanyl congeners, the clinical importance of renal failure is less marked.

Morphine is an opioid with active metabolites that are dependent on renal clearance mechanisms for elimination. Morphine is principally metabolized by conjugation in the liver, and the water-soluble glucuronides (M3G and M6G) are excreted via kidney. The kidney also plays a role in the conjugation of morphine, accounting for nearly 40% of its metabolism.[441] Patients with renal failure can develop very high levels of M6G and life-threatening respiratory depression (Fig. 24.24).[442] In view of these changes induced by renal failure, morphine is not considered a good choice in patients with severely altered renal clearance mechanisms. There are similar concerns for the use of hydromorphone in the setting of renal dysfunction.

The clinical pharmacology of meperidine is also significantly altered by renal failure. Because normeperidine, the main metabolite of meperidine with analgesic and CNS excitatory effect, is subject to renal excretion, the potential CNS toxicity secondary to normeperidine accumulation is especially a concern in patients in renal failure.

In contrast, the clinical pharmacology of the fentanyl congeners is not grossly altered by renal failure, although a decrease in plasma protein binding may potentially alter the free fraction of the fentanyl class of opioids. In the presence of renal impairment, none of fentanyl, alfentanil, sufentanil, and remifentanil deliver a high active metabolite load, or suffer from significantly prolonged clearance.[443] Neither the pharmacokinetics nor the pharmacodynamics of remifentanil is altered by impaired renal function. Levels of GI-90291 that develop during a remifentanil infusion in patients in renal failure are not likely to produce any clinically significant effects.

HEPATIC FAILURE

Even though the liver is the metabolic organ primarily responsible for opioid biotransformation, the degree of liver failure typically observed in perioperative patients, with the exception of patients undergoing liver transplantation, does not have a major impact on the pharmacokinetics of most opioids. In addition to reduced metabolic capacity (i.e., cytochrome P-450 system and conjugation), liver disease may also lead to reductions in hepatic blood flow, hepatocellular mass, and plasma protein binding. The increase in total body water and the edema of advanced liver disease may alter the distribution characteristics of a drug. Enzyme induction such as observed in early alcoholism can actually increase metabolic capacity of the liver.

Morphine pharmacokinetics is relatively unchanged by developing liver disease, such as liver cirrhosis and hepatic carcinoma, because of the substantial compensatory extrahepatic metabolism of morphine. A reduction in hepatic blood flow would be expected to slow the decline of morphine plasma concentrations. After liver resection, M6G/morphine and M3G/morphine ratios were significantly reduced and circulating morphine concentration was increased mainly due to a lower morphine clearance.[444] In patients with cirrhosis, the metabolism of meperidine is decreased, leading to accumulation of the parent drug and possible CNS depressive effects similar to hepatic encephalopathy. Although the elimination of normeperidine is decreased as well in these patients, the ratio of normeperidine to meperidine is generally low, and the opioid effects of meperidine usually predominate.[445] The disposition of fentanyl and sufentanil appears to be unaffected in liver diseases.[446] Reductions in liver blood flow that result from either liver disease or some other disorder (e.g., shock) can affect the pharmacokinetic parameters of alfentanil, fentanyl, and sufentanil. It was demonstrated that there was a significant decrease in clearance of alfentanil in patients with mild to moderate cirrhosis compared with volunteers from the historical control group.[447] Remifentanil is an opioid whose pharmacokinetics is completely unchanged by liver disease (Fig. 24.25).[448] Its kinetics does not change during the anhepatic phase of orthotopic liver transplantation.[449] It was reported that 0.25 to 0.5 μg/kg/min remifentanil could provide perioperative analgesia without neurological deterioration in a patient suffering from chronic hepatic failure with mild encephalopathy.[450]

In summary, a reduction in renal function may have the greatest effects on morphine due to a decrease in capacity for extrahepatic glucuronidation and clearance. Therefore, fentanyl may be a safer choice in renal failure patients due to their lack of active metabolites. In contrast, only under conditions of severe hepatic failure does one observe clinically significant changes in morphine or fentanyl clearance.

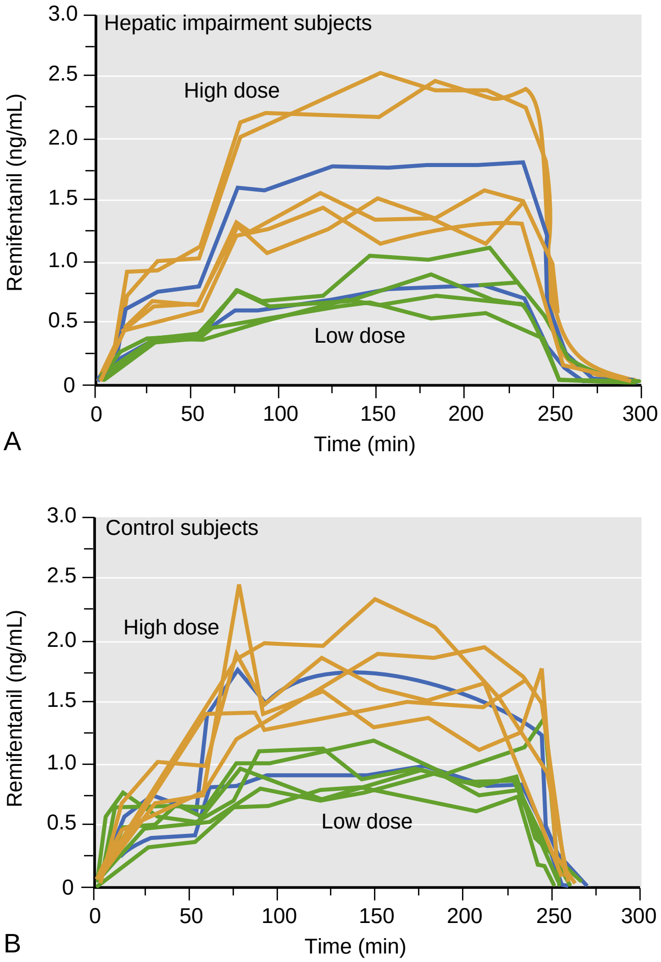

Fig. 24.25 Time-dependent changes of blood concentration of remifentanil in patients with liver disease (A) and in control subjects (B). In the low-dose group, remifentanil was infused at 0.0125 μg/kg/min for 1 hour and then 0.025 μg/kg/min for 3 hours. In the high-dose group, the infusion rate of remifentanil was 0.025 μg/kg/min for 1 hour and then 0.05 μg/kg/min for 3 hours. (From Dershwitz M, Hoke JF, Rosow CE, et al. Pharmacokinetics and pharmacodynamics of remifentanil in volunteer subjects with severe liver disease. *Anesthesiology*. 1996;84:812–820.)

Cardiopulmonary Bypass

CPB produces significant alterations in the pharmacokinetics of most opioids. These alterations are a result of CPB-induced modifications in distribution volumes (secondary to priming), changes in acid-base balance, organ blood flow, plasma protein concentrations, and body temperature. The binding of drugs to components of the bypass circuit can also alter opioid pharmacokinetics.

When morphine is given as a premedicant before cardiac anesthesia, its concentrations decline significantly on initiation of CPB. Miller et al. examined the effect of CPB on plasma fentanyl concentration and showed that total concentration of fentanyl in plasma was significantly decreased and the unbound fraction of fentanyl rose on initiation of CPB.[451] The total fentanyl concentration remained relatively stable during bypass until near the end of CPB when the mean total concentration increased, coinciding with rewarming. Population pharmacokinetic modeling applied to concentration-versus-time data from patients undergoing coronary artery bypass grafting using CPB demonstrated that the effect of CPB on fentanyl pharmacokinetics is clinically insignificant, and that a simple three-compartment model accurately predicts fentanyl concentrations throughout surgery using CPB.[452] Elimination of alfentanil is prolonged by CPB primarily because of increased distribution. It was reported that the volume of distribution in steady state (Vd_{ss}) and the volume of central compartment for alfentanil were significantly greater in the CPB groups, compared to the nonbypass group.[453] However, the elimination half-life (T1/2β) of alfentanil did not differ significantly between the normothermic CPB, hypothermic CPB, and nonbypass groups. Between the normothermic and hypothermic CPB groups no significant differences in Vd_{ss}, clearance, or T1/2β were found. The free fraction of alfentanil during CPB remains constant despite complex changes in binding protein concentrations.[454] In adult patients undergoing elective myocardial revascularization with hypothermic CPB who received continuous infusions of remifentanil 1.0 to 2.0 µg/kg/min, no evidence of accumulation or sequestration was found.[427] Russell et al. reported that normothermic CPB did not significantly affect the clearance of remifentanil, but hypothermic CPB reduced it by an average of 20%, and this was attributed to the effect of temperature on blood and tissue esterase activity.[455] In pediatric patients undergoing CPB for repair of atrial septal defect, there was no change in the Vd_{ss}, the volume of the central compartment, T1/2α, and T1/2β, but clearance values of remifentanil increased 20% in the postbypass period.[456] In patients undergoing coronary artery bypass graft surgery with hypothermic CPB receiving continuous infusion of remifentanil, the volume of distribution increased by 86% with institution of CPB and remained increased after CPB, and elimination clearance decreased by 6.37% for each degree from 37°C.[457] Thus, although clearance of remifentanil reduces during CPB, remifentanil remains a very short-acting drug even during CPB.

Acid-Base Changes

It was demonstrated that pH changes influence the protein binding of fentanyl, sufentanil, and alfentanil, resulting in an increase in protein binding with alkalosis and a decrease with acidosis. These effects are greater for fentanyl than sufentanil and sufentanil than alfentanil. Relative changes in the free-drug fraction with pH variation from 7.4 to 7.0 were much higher for fentanyl (52%) when compared with sufentanil (29%) and alfentanil (6%). The pH dependence of plasma protein binding of the opioids significantly correlates with their partition between an organic and aqueous phase, suggesting the hydrophobic character of the interaction between plasma proteins and opioids. Increased ionization decreases the amount of fentanyl available for hepatic metabolism or renal excretion. Intraoperative hyperventilation during surgical procedures can significantly influence the pharmacokinetics of sufentanil resulting in an increased distribution volume and a prolonged elimination half-time.

Thus, both intraoperative respiratory alkalosis and respiratory acidosis, especially in the immediate postoperative period, can prolong and exacerbate opioid-induced respiratory depression.

Hemorrhagic Shock

It is a common practice to administer reduced doses of opioids to patients suffering from hemorrhagic shock to minimize adverse hemodynamic consequences and to prevent prolonged opioid effect. This is at least partially attributable to a pharmacokinetic mechanism. Analysis with pigs receiving fentanyl suggested that central clearance and central- and second-compartment distribution volumes were significantly reduced in hemorrhagic shock, resulting in higher fentanyl concentrations for any given dosages and prolonged context-sensitive half-time (Fig. 24.26).[458] Hemorrhagic shock also altered pharmacokinetics of remifentanil, suggesting that less remifentanil would be required to maintain a target plasma concentration (Fig. 24.27).[459] However, because of its rapid metabolism, changes in context-sensitive half-time are small. In a stepwise hemorrhage model of pigs receiving total intravenous anesthesia with remifentanil (0.5 µg/kg/min) and propofol (6 mg/kg/h after 2 mg/kg bolus), the plasma remifentanil concentration showed a threefold greater increase than that of propofol.[460] Thus, the remifentanil dose should be reduced substantially compared with propofol during total intravenous anesthesia for patients with significant blood loss.

The graph indicates spectral edge measurements for control animals and for animals with hemorrhagic shock, respectively. (From Johnson KB, Kern SE, Hamber EA, et al. Influence of hemorrhagic shock on remifentanil: a pharmacokinetic and pharmacodynamic analysis. *Anesthesiology*. 2001;94:322–332.)

Genetic Variations in Opioid Metabolism

All opioid drugs are substantially metabolized mainly by cytochrome P450 (CYP) and to a lesser extent by UDP-glucuronosyltransferases (UGTs). Although CYP3A4 is involved in the metabolism of many of the opioids, it is the role of the highly polymorphic CYP2D6 that is of greater clinical interest with respect to the weaker opioids (codeine, dihydrocodeine, oxycodone, hydrocodone, and tramadol), because of the formation of their more potent hydroxyl metabolites (morphine, dihydromorphine, oxymorphone, and hydromorphone), which have about a 30-fold higher affinity for the μ-receptor. The CYP2D6 gene is highly polymorphic, with 100 allelic variants identified, and enzymatic activity of some alleles may be either significantly high or low. In the case of a variant more rapidly producing metabolites of higher affinity there exists the possibility of administering an unintended opioid overdose. This has been especially of concern for the use of codeine-containing products in pediatric populations resulting in changes in prescribing practice. Alternately, variants leading to low production of potent metabolites may result in subtherapeutic outcomes.[461] Finally, UGTs mediate mainly the formation of glucuronides from buprenorphine, codeine, dihydrocodeine, dihydromorphine, hydromorphone, morphine, naloxone, naltrexone, and oxymorphone. UGT2B7 gene is polymorphic, and less than 20 allelic variants have been identified. It is possible that differences in metabolic activity among UGT alleles affect pharmacokinetics of opioids.[461]

Anesthetic Techniques Using Opioids

ANALGESIA

Opioids are frequently used to relieve pain during monitored anesthesia care and regional anesthesia. A single bolus administration of opioids can provide significant pain relief. Morphine is slow in onset and does not allow rapid titration to effect. Meperidine (50-100 mg IV) produces variable degrees of pain relief and is not always effective in patients with severe pain. IV boluses of fentanyl (1-3 μg/kg), alfentanil (10-20 μg/kg), or sufentanil (0.1-0.3 μg/kg) can produce potent and short-lasting analgesia. Infusion rates range from 0.01 to 0.05 μg/kg/min for fentanyl, 0.0015 to 0.01 μg/kg/min for sufentanil, 0.25 to 0.75 μg/kg/min for alfentanil, and 0.05 to 0.25 μg/kg/min for remifentanil. Plasma concentrations of opioids necessary for various purposes are listed in Table 24.8.

Changes in the excitability of central neurons play an important role in establishment of pain. In rats, low doses of fentanyl block the synaptic form of central sensitization in the rat spinal cord in vivo, suggesting the possibility of preemptive analgesia by fentanyl, but higher doses do not have this effect.[462] In fact, dose escalation of fentanyl or other potent opioids may produce a hyperalgesic state—mentioned previously. Reductions in postoperative pain and improved recovery have been attributed to preemptive analgesia with either epidural fentanyl or bupivacaine after radical prostatectomy.[463] In contrast, in patients undergoing transperitoneal tumor nephrectomy, preoperative intravenous administration of a combination of morphine, ketamine, and clonidine failed to exert a clinically relevant effect on postoperative pain.[464] Aida et al. reported that the effectiveness of preemptive analgesia varies according to the type of surgery, and preemptive analgesia with epidural morphine was reliably effective in limb and breast surgeries but ineffective in abdominal surgery.[465] A meta-analysis demonstrated that the results of preemptive analgesia with systemic administration of opioids are equivocal.[466] Thus, whether or not preemptive analgesia can be effectively achieved clinically by the early administration of opioids remains uncertain and may be highly context specific.

Patient-controlled analgesia (PCA) with opioids has become a widely accepted technique in which to provide postoperative analgesia, but pharmacokinetic optimization of opioid treatment in acute pain is a complex matter. Without considering effect-site drug concentrations over time, the choice of opioid and the amount, method, and frequency of its administration cannot be optimal. Morphine and fentanyl are often used for PCA therapy, and piritramide is also frequently used for PCA in European countries. A double-blind randomized study demonstrated that effect-site target-controlled remifentanil PCA with a slow and progressive adapted algorithm is feasible in young women undergoing uterine artery embolization.[467] Combination of opioid with other drugs might be a method for improvement of PCA. For thoracic surgery, addition of ketamine to opioid for intravenous PCA was superior to intravenous PCA opioid alone, whereas the effect of added ketamine was not significant for orthopedic or abdominal surgery.[468] Despite the utility of an opioid-based PCA, critical considerations must also be made as to an individual patient's relative risk of opioid-induced respiratory depression with appropriate oversight and monitoring.

TABLE 24.8 Range of Approximate Plasma (or Whole Blood for Remifentanil) Opioid Concentration

	Fentanyl (ng/mL)	Sufentanil (ng/mL)	Alfentanil (ng/mL)	Remifentanil (ng/mL)
Predominant agent	15-30	5-10	400-800	—
Major surgery	4-10	1-3	200-400	2-4
Minor surgery	3-6	0.25-1	50-200	1-3
Spontaneous ventilation	1-3	<0.4	<200	0.3-0.6
Analgesia	1-2	0.2-0.4	50-150	0.2-0.4

From Bailey PL, Egan TD, Stanley TH. Intravenous opioid anesthetics. In: Miller RD, ed. *Anesthesia*. 8th ed. Philadelphia: Saunders; 2015. An imprint of Elsevier Inc,, p. 895.

SEDATION

Critically ill subjects in the intensive care unit (ICU) often experience anxiety and agitation while being exposed to numerous stressful or noxious stimuli. ICU patients generally require a combination of analgesia and sedation to relieve their state of anxiety, improve adaptation to the endotracheal tube, and aid compliance with mechanical ventilation. Morphine, fentanyl, and sufentanil are frequently used intravenous analgesic agents in the ICU. A randomized double-blind study indicated that remifentanil (0.15 µg/kg/min) and morphine (0.75 µg/kg/min) could provide comparable levels of sedation, and the remifentanil-based regimen allowed a more rapid emergence from sedation and facilitated earlier extubation.[469] However, use of ultrapotent opioid agents such as remifentanil may also drive tolerance development and OIH—as discussed previously.

BALANCED ANESTHESIA

Anesthesia with a single agent can often require doses that produce excessive hemodynamic depression. Alternately, "balanced anesthesia" with a balance of agents and techniques can be used to more selectively direct different components of anesthesia (i.e., analgesia, amnesia, muscle relaxation, and abolition of autonomic reflexes with maintenance of homeostasis). For example, inclusion of an opioid as a component of balanced anesthesia can reduce preoperative pain and anxiety, decrease somatic and autonomic responses to airway manipulations, improve hemodynamic stability, lower requirements for inhaled anesthetics, and provide immediate postoperative analgesia. Opioids interact synergistically and markedly reduce the dose of propofol and other sedative-hypnotics required for loss of consciousness and during noxious stimulation such as skin incision (Fig. 24.28).[470] Although the intent of combining opioids with sedative-hypnotics and/or volatile anesthetics is to produce anesthetic conditions with stable hemodynamics prior to as well as after noxious stimulation, this ideal is not always achieved.[471,472]

The timing, rate of administration, and dose of supplemental opioids should also be tailored to the specific condition of the patient and the expected duration of the operation in order to avoid problems. Giving a large dose of any opioid shortly before the end of surgery is very likely to result in postoperative respiratory depression. However, analgesic concentrations of opioids have little effect on the MAC awake of inhaled anesthetics.[473]

The ideal opioid would permit rapid titration, prevent unwanted responses to noxious stimuli, require little supplementation, not depress cardiovascular function, permit the return of adequate spontaneous ventilation in a timely manner, and produce effective postoperative analgesia with minimal side effects. Alfentanil and remifentanil provide the greatest ability to titrate opioids rapidly because of their extremely rapid time to onset (1-2 minutes) of peak effect. Sufentanil, alfentanil, and remifentanil are arguably superior to fentanyl in most respects. Antagonism of opioid action with naloxone for troublesome respiratory depression is required less frequently after alfentanil and sufentanil compared with fentanyl. Pharmacologic antagonism is not required after remifentanil administration because of its short half-life.

Fentanyl

Anesthetic induction is usually achieved by combining a loading dose of fentanyl (2-6 µg/kg) with a sedative-hypnotic, most commonly thiopental or propofol, and a muscle relaxant. Maintenance of anesthesia can be achieved with low concentrations of potent inhaled anesthetics, and additional fentanyl (intermittent boluses of 25-50 µg every 15-30 minutes or a constant infusion of 0.5-5.0 µg/kg/h).

The plasma concentration of fentanyl required for postoperative analgesia was approximately 1.5 ng/mL.[474] MAC of isoflurane at skin incision can be reduced by 50% and 63%

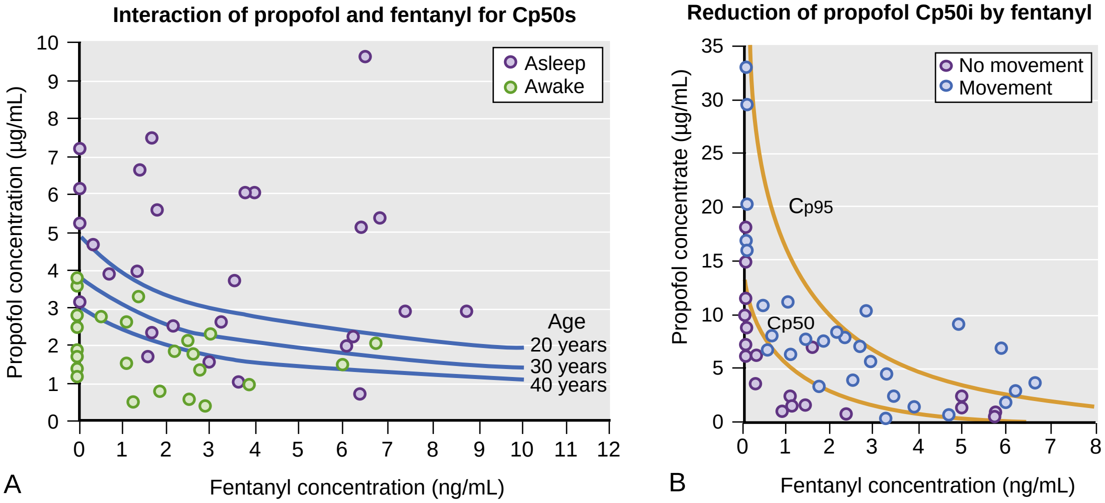

Fig. 24.28 (A) Measured arterial propofol and fentanyl concentrations at which patients did and did not respond to a verbal command at 10 minutes after the initiation of the infusion of these drugs. The *solid lines* represent the modeled concentration of propofol, according to decade of age when combined with the measured fentanyl concentrations, at which 50% of patients did not respond to verbal command (Cp50s). (B) Reduction by increasing concentration of fentanyl of propofol concentration at which 50% or 95% of patients did not move at skin incision (Cp50i and CP95i, respectively). The *solid lines* represent logistic regression solution. (From Smith C, McEwan AI, Jhaveri R, et al. The interaction of fentanyl on the Cp50 of propofol for loss of consciousness and skin incision. *Anesthesiology*. 1994;81:820–828.)

with plasma fentanyl concentrations of 1.67 and 3.0 ng/mL, respectively.[121] Increasing plasma fentanyl concentrations from 3.0 to 10 ng/mL only further reduced the MAC of isoflurane from 63% to 82%. Intraoperative requirement of propofol for hypnosis is also reduced by fentanyl. In patients undergoing spine fusion, to keep the mean arterial pressure within 15% of the control value when fentanyl was infused to keep the plasma concentration at 0, 1.5, 3.0, and 4.5 ng/mL, average propofol infusion rates were 10.1 ± 2.5 (mean ± SD), 7.5 ± 1.2, 5.7 ± 1.1, and 4.9 ± 1.2 mg/kg/h, respectively.[475]

Opioid pharmacokinetics and pharmacodynamics vary considerably among patients. It was reported that fentanyl dose based on total body weight may cause overdosing in obese patients.[474] As discussed previously, considerations for dosing based on lean body weight and/or ideal body weight may have merit in this context. Nevertheless, a balanced technique with fentanyl, titrating the opioid in anticipation of various stimuli and patient responses with pharmacokinetic guidelines in mind, will often result in a stable hemodynamic course and rapid awakening in a pain-free patient. Repeated doses or continuous infusions of fentanyl are most likely to result in significant depression of spontaneous ventilation.

Alfentanil

Because alfentanil penetrates the brain so rapidly, equilibration of alfentanil between plasma and CNS can be achieved while plasma alfentanil levels are relatively low compared with sufentanil and fentanyl. This property explains how low doses (10-30 μg/kg) of alfentanil, administered just before or simultaneously with a sedative-hypnotic, are effective.

Alfentanil (25-50 μg/kg IV), followed by small titrated sleep doses of any sedative-hyponic (e.g., 50-100 mg sodium thiopental), is usually successful in preventing significant hemodynamic stimulation from laryngoscopy and intubation. The optimum dose of alfentanil, coadministered with 2.5 mg/kg propofol, when inserting a classic laryngeal mask airway was 10 μg/kg.[476] Further opioid supplementation can be achieved with an alfentanil infusion (0.5-2.0 μg/kg/min) or intermittent boluses of alfentanil (5-10 μg/kg) for shorter procedures. In balanced anesthetic techniques in which potent inhaled anesthetics are also employed, relatively low plasma alfentanil concentrations (e.g., 29 ng/mL) can reduce the MAC of isoflurane by approximately 50%.[123] The EC50 of alfentanil during propofol anesthesia, in which plasma concentration of propofol was kept at target concentrations of 3 μg/mL, was 92 ng/mL for intubation, 55 ng/mL for skin incision, 84 ng/mL for the opening of the peritoneum, and 66 ± 38 ng/mL for the intraabdominal part of surgery.[477] It was reported that hemodynamic changes induced by propofol might have an important influence on the pharmacokinetics of alfentanil. Propofol (target concentration, 1.5 μg/mL) decreased the elimination clearance of alfentanil by 15%, rapid distribution clearance by 68%, slow distribution clearance by 51%, and lag time by 62%.[478] Alfentanil infusions or repeated doses should be minimized 15 to 30 minutes prior to the end of surgery in order to avoid problematic residual respiratory depression.

Sufentanil

CP_{50} for prevention of hemodynamic responses to laryngoscopy and tracheal intubation was 1.08 ng/mL with a range of 0.73 to 2.55 ng/mL. In combination with propofol for induction of anesthesia in children, bolus administration of sufentanil 0.3 μg/kg can completely abolish the cardiovascular response to tracheal intubation.[479] In healthy normotensive adult patients, a bolus sufentanil 0.1 μg/kg followed by a continuous infusion at 0.08 μg/kg/min for at least 5 minutes proved to be effective for blunting the cardiovascular response to intubation.[480] Maintenance of anesthesia can be achieved with sufentanil (intermittent boluses, 0.1-0.25 μg/kg, or constant infusion, 0.5-1.5 μg/kg/h). The CP_{50} for sufentanil during skin incision (2.08 ± 0.62 ng/mL) is twice as great as that for intubation in unpremedicated patients.[481] CP_{50} value ratios at skin incision for sufentanil, fentanyl, and alfentanil are approximately 1:2:150 and represent different, and probably more accurate, potency ratios than those traditionally published based on drug dose. In patients undergoing coronary artery bypass grafting, sufentanil greater than 1.25 ± 0.21 ng/mL reduced isoflurane requirements to less than 0.5% through the operation.[482]

Remifentanil

Very short duration of action of remifentanil mandates that an infusion (0.1-1.0 μg/kg/min) be started prior to or soon after a small bolus dose to ensure sustained opioid effect. Maintenance infusion rates of remifentanil range from 0.1 to 1.0 μg/kg/min for balanced anesthesia. Remifentanil can reliably suppress automatic, hemodynamic, and somatic responses to noxious stimulation and allows the most predictable and rapid trouble-free emergence from anesthesia without postoperative respiratory depression. Infusion rates of 0.1 ± 0.05 μg/kg/min should permit the return of spontaneous ventilation and responsiveness with maintenance of analgesia. A randomized, double-blind, placebo-controlled study demonstrated that combination of 0.05-0.1 μg/kg/min remifentanil and 2 mg midazolam provided effective sedation and analgesia during outpatient surgical procedures performed under local anesthesia.[483]

Associated with emergence from remifentanil anesthesia, the need for alternative analgesic therapies should be anticipated and administered in a timely fashion. Exposure to high doses of remifentanil may paradoxically reduce the pain threshold after its discontinuation, resulting in postoperative hyperalgesia, which is known to be associated with acute and persistent pain. It was reported that perioperative administration of morphine (0.15 or 0.25 mg/kg IV) or fentanyl (0.15 mg) did not provide entirely adequate immediate postoperative pain control after remifentanil-based anesthesia in major abdominal surgery.[484,485] Administration of ketamine (0.15 mg/kg followed by 2 μg/kg/min) decreased intraoperative remifentanil use during abdominal surgery and postoperative morphine consumption without increasing the incidence of side effects.[486] In children undergoing strabismus surgery, combination of sevoflurane (2.5%) and remifentanil (1 μg/kg followed by 0.1-0.2 μg/kg/min) showed less frequent postoperative vomiting but higher postoperative pain scores compared with fentanyl (2 μg/kg followed by 1 μg/kg every 45 minutes).[487]

Postoperative pain relief with low-dose remifentanil infusion was also reported. After general anesthesia with propofol (75 mg/kg/min) and remifentanil (0.5-1.0 mg/kg/min) for abdominal or thoracic surgery, continuous infusion of remifentanil (0.05 or 0.1 mg/kg/min) provided adequate analgesia.[488]

TOTAL INTRAVENOUS ANESTHESIA

Many different IV anesthetic and analgesic compounds can be employed in a number of combinations to provide TIVA. Most commonly, an opioid is combined with another drug more likely to provide hypnosis and amnesia. For example, combination of alfentanil and propofol can produce desirable TIVA. Alfentanil provides analgesia and hemodynamic stability while blunting responses to noxious stimuli. On the other hand, propofol provides hypnosis and amnesia and is antiemetic. Anesthetic induction with alfentanil (25-50 μg/kg) and propofol (0.5-1.5 mg/kg) followed by infusions of 0.5 to 1.5 μg/kg/min of alfentanil and 80 to 120 μg/kg/min of propofol will produce complete anesthesia for a variety of procedures. It is proposed that alfentanil concentrations as low as 85 ng/mL, when combined with a blood propofol concentration of 3.5 μg/mL, can produce both optimal anesthetic conditions and speed of recovery.[489] Stanski and Shafer suggested that bolus doses and initial infusion rates would be 30 μg/kg and 0.35 μg/kg/min for alfentanil and 0.7 mg/kg and 180 μg/kg/min for propofol.[490] Recognizing that these calculations were based on EC_{50} data in patients undergoing only moderately painful procedures, anesthesiologists should adjust these doses accordingly. In patients undergoing ear-nose-throat surgery, TIVA with remifentanil and propofol provided a more rapid respiratory recovery after brief surgical procedures, compared with TIVA with alfentanil and propofol.[491]

Maintenance infusions vary according to patient condition and surgical stimuli. Propofol (75-125 μg/kg/min) and alfentanil (1.0-2.0 μg/kg/min) were initially recommended. Propofol infusions should be terminated 5 to 10 minutes before anticipated patient awakening. Alfentanil infusion rates do not need to be less than 0.25 to 0.5 μg/kg/min until surgery is terminated. A multicenter evaluation demonstrated that in patients of elective inpatient surgery remifentanil 1 μg/kg IV followed by 1.0 μg/kg/min, when combined with propofol 75 μg/kg/min, effectively controlled responses to tracheal intubation.[492] Reduction of remifentanil infusion rate to 0.25-0.40 μg/kg/min after tracheal intubation was also recommended. Although midazolam-opioid combinations can also provide complete anesthesia, midazolam-alfentanil TIVA has not been found to compare favorably to propofol-alfentanil TIVA even with flumazenil reversal of benzodiazepine actions.[493]

TIVA techniques are especially useful when delivery of inhaled agents is compromised. By keeping the goals of balanced anesthesia in mind, combining modern opioids and other drugs, utilizing infusion pumps, and employing an increased understanding of pharmacokinetics, clinicians can successfully perform a variety of TIVA techniques. Approximate opioid doses and infusion rates for TIVA are listed in Table 24.9.

OPIOID-BASED (HIGH-DOSE OPIOID) ANESTHESIA FOR CARDIAC SURGERY

Opioids can be administered as the primary anesthetic in opioid-based anesthetic techniques. High-dose opioid anesthesia was introduced as a stress-free anesthetic method for cardiac surgery. High-dose opioid anesthesia was first performed by the use of morphine, and fentanyl and sufentanil have been recommended later. However, several factors have diminished the popularity of high-dose opioid anesthesia, even in cardiac anesthesia. These include the lack of evidence substantiating any significant outcome benefit associated with the use of large doses of opioids, the added drug costs, and the trend toward "fast-track" approaches to the cardiac patient that can be impeded by large doses of opioids. However, opioids, particularly when administered by continuous infusion, are still among the most effective anesthetics for patients undergoing cardiac or other extensive operations.

TABLE 24.9 Approximate Opioid Loading (Bolus) Doses, Maintenance Infusion Rates, and Additional Maintenance Doses for Total Intravenous Anesthesia

	Loading Dose (μg/kg)	Maintenance Infusion Rate	Additional Boluses
Alfentanil	25-100	0.5-2 μg/kg/min	5-10 μg/kg
Sufentanil	0.25-2	0.5-1.5 μg/kg/h	2.5-10 μg
Fentanyl	4-20	2-10 μg/kg/h	25-100 μg
Remifentanil	1-2	0.1-1.0 μg/kg/min	0.1-1.0 μg/kg

From Bailey PL, Egan TD, Stanley TH. Intravenous opioid anesthetics. In: Miller RD, ed. *Anesthesia*. 8th ed. Philadelphia: Saunders; 2015. An imprint of Elsevier Inc., p. 897.

In an attempt to decrease the costs of cardiac surgery, fast-track programs have become popular. Engoren et al. reported that the more expensive but shorter-acting opioids, sufentanil and remifentanil, produced equally rapid extubation, similar stays, and similar costs to fentanyl, indicating that any of these opioids can be recommended for fast-track cardiac surgery.[494]

Fentanyl

Many different techniques have been used to achieve anesthesia with fentanyl.[495,496] Rapid or slow bolus injections of fentanyl ranging from 5 to 75 μg/kg will establish plasma fentanyl concentrations (10-30 ng/mL) that are often sufficient to provide stable hemodynamics throughout the induction/intubation sequence. Continuous infusions of fentanyl for cardiac surgery range from 0.1 to 1.0 μg/kg/min up to or continuing through CPB. High-dose fentanyl anesthesia has also proved effective and safe for pediatric heart surgery. It was indicated that fentanyl 25 to 50 μg/kg combined with isoflurane 0.2% to 0.4% was sufficient to obtund hemodynamic and stress responses in the pre-CPB phase of open heart surgery in infants and young children (Fig. 24.29).[497] It was reported that 57 out of 59 eligible patients were successfully extubated at 34 ± 14 minutes after termination of fentanyl (total dose, 127 ± 64 μg/kg) with naloxone (total bolus, 3.4 ± 2.6 μg/kg), and recovered fully without ventilatory support under the naloxone infusion, which was terminated at 11 ± 7 hours.[498] These results suggest that naloxone infusion with individual dose titration can facilitate the use of high-dose opioid anesthesia, maintaining the advantage of this anesthesia. It was shown that high-dose fentanyl (50 μg/kg) is not associated

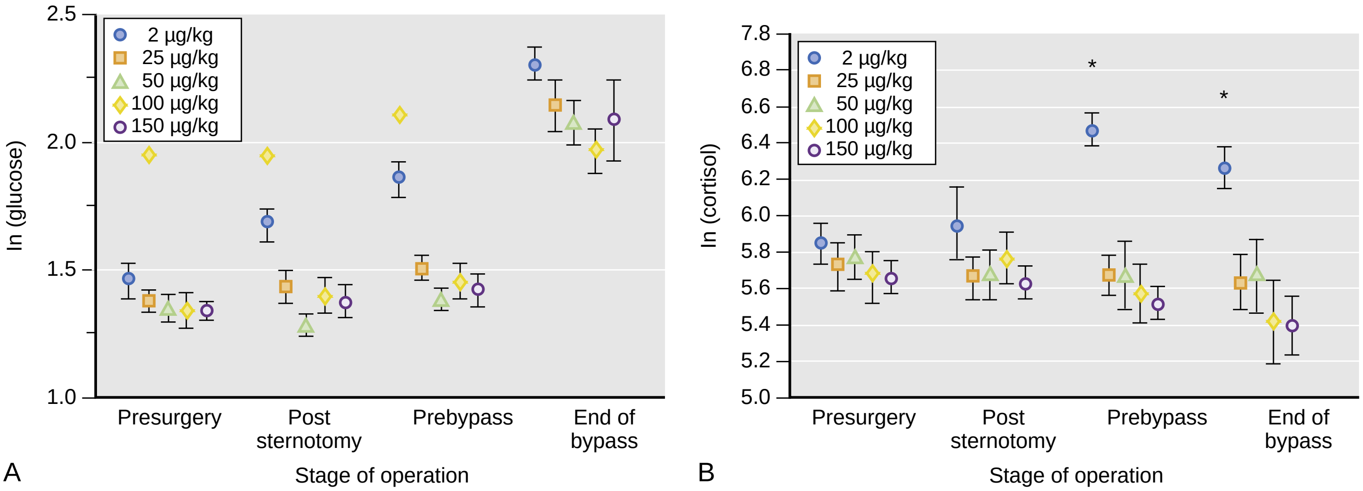

Fig. 24.29 Suppression of stress responses in the prebypass phase of open heart surgery in infants and young children by fentanyl combined with low concentration (0.2%-0.4%) of isoflurane. Mean (± SE) natural logarithm (ln) for glucose (A) or ln for cortisol (B) versus stage of surgery for each dose of fentanyl. The values for the 2 µg/kg group indicated by *asterisks* were significantly higher ($P < .01$) than in the other groups. (From Duncan HP, Cloote A, Weir PM, et al. Reducing stress responses in the pre-bypass phase of open heart surgery in infants and young children: a comparison of different fentanyl doses. *Br J Anaesth.* 2000;84:556–564.)

with a difference in the incidence of postoperative cognitive dysfunction at 3 or 12 months after coronary artery bypass surgery in the elderly, whereas low-dose fentanyl (10 µg/kg) leads to shorter postoperative ventilation times and may be associated with a greater incidence of postoperative cognitive dysfunction 1 week after surgery.[499]

Sufentanil

Advantages of high-dose sufentanil include more rapid induction, better blunting or elimination of hypertensive episodes, greater reduction in left ventricular stroke work, with higher cardiac outputs and more stable hemodynamics intraoperatively and/or postoperatively. Induction doses of sufentanil range from 2 to 20 µg/kg administered as a bolus or infused over 2 to 10 minutes. Total doses of sufentanil employed in high-dose techniques usually range from 15 to 30 µg/kg. However, no additional benefit could be demonstrated in terms of hemodynamic control or EEG signs by increasing the dose of sufentanil from 3 to 15 µg/kg for the induction of anesthesia in patients premedicated with lorazepam.[500] The amount of sufentanil required can be markedly influenced by the supplements employed concomitantly. For patients undergoing coronary artery surgery, induction (0.4 ± 0.2 µg/kg) and total maintenance (2.4 ± 0.8 µg/kg) doses of sufentanil were used in combination with propofol (1.5 ± 1 mg/kg for induction and 32 ± 12 mg/kg total). Interestingly, sufentanil requirements tripled when midazolam was employed instead of propofol.[501] Maintenance of anesthesia, utilizing infusion of sufentanil (1.0-2.0 µg/kg/h), in a balanced anesthetic technique, achieves the advantages of opioid-based anesthesia and avoids prolonged opioid action into the postoperative period.

Remifentanil

Remifentanil has been employed in cardiac anesthesia.[455] It was shown that induction with remifentanil 2 µg/kg with propofol and maintenance with remifentanil at 0.25 or 0.5 µg/kg/min provided appropriate anesthesia for minimally invasive coronary artery bypass surgery with rapid awakening and tracheal extubation (Fig. 24.30).[502] Kazmaier et al. compared high-dose remifentanil (2.0 µg/kg/min) and remifentanil 0.5 µg/kg/min combined with propofol (target-controlled infusion aiming at a plasma concentration of 2.0 µg/mL) in patients undergoing elective coronary artery bypass grafting.[503] It was demonstrated that high-dose remifentanil reduces stroke volume index,

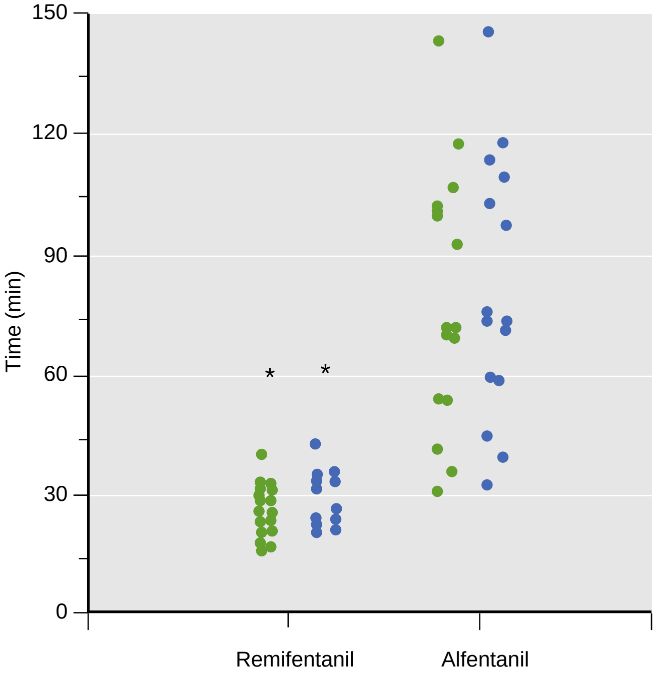

Fig. 24.30 Times to awakening *(green circles)* and tracheal extubation *(blue circles)* in patients who underwent minimally invasive direct coronary artery bypass surgery after intravenous anesthesia with remifentanil and propofol or alfentanil and propofol. (From Ahonen J, Olkkola KT, Verkkala K, et al. A comparison of remifentanil and alfentanil for use with propofol in patients undergoing minimally invasive coronary artery bypass surgery. *Anesth Analg.* 2000;90:1269–1274.)

heart rate, mean arterial pressure, myocardial blood flow, and myocardial oxygen uptake and its effects do not differ from those of remifentanil/propofol anesthesia. Geisler et al. examined efficacy and safety of high-dose remifentanil anesthesia in patients undergoing coronary artery bypass graft surgery.[504] It was demonstrated that continuous infusions of remifentanil 1.0 to 2.0 μg/kg/min in combination with propofol 3 mg/kg/h provided profound suppression of responses to surgical stimuli in the majority of patients, but there was a high incidence of muscle rigidity when remifentanil was used to induce anesthesia. They concluded that there was no apparent advantage in starting the remifentanil infusion rate above 1.0 μg/kg/min and remifentanil is not suitable for use as a sole induction agent.

OTHER APPLICATIONS OF OPIOIDS

Transdermal Therapeutic System

Transdermal drug delivery generally requires high solubility in both water and oil, low molecular weight, high potency, and little or no skin irritation. Fentanyl is available in a transdermal therapeutic system (TTS). Potential advantages of delivering fentanyl transdermally include no first-pass drug metabolism by the liver, improved patient compliance, convenience and comfort, and consistent analgesia. Doses of TTS fentanyl include 25, 50, 75, and 100 μg/h and achieve blood levels ranging from less than 1.0 to 2.0 ng/mL, although significant variability exists. Pharmacokinetics of transdermally-delivered fentanyl (50 μg/h) was compared in 10 young adult (25-38 years) and eight elderly (64-82 years) patients.[505] It was shown that the mean half-time (time for plasma concentrations to double after patch application) was 4.2 hours and 11.1 hours and mean maximum plasma concentrations were 1.9 ng/mL and 1.5 n/mL, in the younger and elderly groups, respectively. There were no differences in the time at which maximum plasma concentrations occurred nor elimination half-life after patch removal. Elevated body temperature and/or application of external warming devices can accelerate either the release of fentanyl from the patch or increase the vascular bed distribution from the subcutaneous tissues. Portenoy et al. demonstrated that steady state serum concentration was obtained by repeated application of TTS fentanyl and the apparent half-life following system removal after repeated application was relatively long presumably due to ongoing absorption from a subcutaneous depot.[506]

Results of clinical trials utilizing TTS fentanyl for postoperative analgesia have demonstrated a high incidence of significant respiratory depression, and this application is not recommended and is contraindicated.[507] In cancer pain, TTS fentanyl offers an interesting alternative to oral morphine, and its effectiveness and tolerability in this indication has been demonstrated by a number of trials.[508] Its usefulness in chronic pain of nonmalignant origin remains to be confirmed in controlled trials just as there is a lack of evidence for the efficacy of chronic oral opioid administration in the treatment of nonmalignant pain. In general, TTS fentanyl produces the same adverse effects as other opioids, mainly sedation, nausea, vomiting, and constipation. In comparison with oral morphine, TTS fentanyl causes fewer gastrointestinal adverse events.

Buprenorphine is suitable for transdermal application because of its properties that facilitate transdermal absorption such as low molecular weight, high lipophilicity, and high potency. Beyond its application in the management of OUD, buprenorphine TDS may be effective for moderate and possibly severe cancer pain.[509] Studies on the use of buprenorphine TTS for severe noncancer pain that is refractory to nonopioid analgesia are emerging. Poulain et al. studied the effect of buprenorphine TDS in patients with cancer pain and demonstrated a reduction in mild–moderate pain scores (from 3.5 ± 2.2 to 1.5 ± 1.5) in the group that received buprenorphine TDS, with worsening of pain scores (from 1.5 ± 1.5 to 2.7 ± 1.9) in the placebo group.[510] The transdermal formulation of buprenorphine in the United States is currently available in 5 dosage strengths: 5, 7.5, 10, 15, and 20 μg/h, and the bioavailability decreases to 15% after a 7-day application.

Iontophoresis

Iontophoresis is a technique by which drug passage through the skin is augmented by an external electric current. Clinically significant doses of morphine and fentanyl can be delivered iontophoretically. The fentanyl hydrochloride iontophoretic transdermal system (fentanyl ITS) is a novel PCA system that has been approved in the USA and Europe for the management of acute, moderate-to-severe postoperative pain.[511] This system allows patients to self-administer preprogrammed doses of fentanyl noninvasively through the use of iontophoretic technology. To assess the efficacy and safety of patient-controlled ITS using fentanyl hydrochloride (40-μg infusion over 10 minutes) compared with a standard intravenous morphine PCA (1-mg bolus every 5 minutes; maximum of 10 mg/h), a prospective randomized controlled parallel-group trial was performed.[512] The results indicated that the fentanyl ITS can provide pain control equivalent to a standard morphine PCA, with a similar incidence of opioid-related adverse events. The fentanyl ITS may offer a number of clinical advantages over existing PCA modalities.[511] Its method of drug delivery avoids the risk of complications from needle-related injuries and infection, and its preprogrammed electronics eliminate the potential for manual programming errors and excessive dosing. In addition, the compact size of the system could enable greater patient mobility following surgery. The patient-controlled ITS with fentanyl has the potential to become a valuable option in the management of acute postoperative pain. Panchal and associates reported that fentanyl ITS was associated with a significantly lower incidence of analgesic gaps, which are defined as periods during which the patient does not have access to analgesia thus contributing to ineffective postoperative pain management, relative to morphine intravenous PCA.[513] Nevertheless, given potential variability in dose delivery and other factors, ITS systems may be restricted to monitored in-hospital facilities.

Transmucosal Drug Delivery

Similar to transdermal drug delivery, transmucosal delivery through the oropharynx and nasopharynx eliminates hepatic first-pass metabolism (drugs are absorbed directly into the systemic circulation) and improves patient comfort, convenience, and compliance.

Buprenorphine, a potent, synthetic morphine analogue with mixed opioid agonist-antagonist properties and a long half-time, is readily absorbed from sublingual mucosal tissues. The portion of the drug that is swallowed is almost completely metabolized by the liver, and only a small fraction can reach the systemic circulation when swallowed. Systemic bioavailability after sublingual buprenorphine is approximately 50% of that following intravenous administration. Sublingual buprenorphine (0.3 mg) was compared with transdermal buprenorphine (5, 10 and 20 μg/h) for osteoarthritis pain in the hips and/or knees and found to provide comparable analgesia.[514] Buccal buprenorphine was introduced and approved by the Food and Drug Administration in 2015 for the management of chronic pain. It is composed of flexible, water-soluble polymeric films that stick to the buccal mucosa and dissolve within a few minutes. The bioavailability of this formulation is 46%–65%, and it is useful in patients who are taking over 80 mg oral morphine sulfate equivalent per day for pain management.[515]

Initial experience with buccal morphine for postoperative analgesia had been promising. However, in female patients undergoing lower abdominal surgical procedures, buccal morphine did not significantly reduce postoperative pethidine consumption, compared with placebo, and all patients receiving buccal morphine reported a taste which reduced its acceptability.[516] Low lipid solubility of morphine makes it an unlikely candidate for effective transmucosal absorption. Opioids with high lipid solubility, such as buprenorphine, fentanyl, and methadone are more effectively absorbed sublingually than those with low lipid solubility such as morphine.

Oral transmucosal fentanyl citrate (OTFC) is a solid dosage form of fentanyl that consists of fentanyl incorporated into a sweetened lozenge on a stick. A portion of fentanyl is absorbed through the oral mucosa, and the rest is swallowed and absorbed through the gastrointestinal tract. The recommended doses range from 5 to 20 μg/kg.[517] OTFC should be administered approximately 30 minutes before surgery (or painful procedure) to obtain peak effect. Plasma concentrations after OTFC administration peak at 2.0 ± 0.5 ng/mL, 15 to 30 minutes after OTFC administration, then decline to less than 1 ng/mL an hour later.[518] Unlike transdermal fentanyl, OTFC leaves no significant depot in the mucosal tissues after it is removed. The systemic bioavailability of OTFC is 50% and reflects both buccal and gastrointestinal absorption. OTFC bioavailability is similar to that of buprenorphine (55%), but much greater than buccal morphine and other opioids with low lipid solubility. Egan et al. demonstrated that the pharmacokinetics of OTFC did not change with repeated dosing and the decline of plasma concentration was as rapid as when administered intravenously (Fig. 24.31).[519] Furthermore, Kharasch et al. reported that the pharmacokinetics of OTFC were not altered in older volunteers (67 ± 6 years), and no change in OTFC dosing in the elderly would appear necessary.[520] Peak fentanyl concentration and clinical effects after OTFC were minimally affected by hepatic/intestinal CYP3A induction by rifampicin and intestinal CYP3A inhibition by grapefruit juice, suggesting that first-pass metabolism minimally influences OTFC bioavailability.[521] Preoperative OTFC was reported to be effective for postoperative analgesia in pediatric tonsillectomy patients.[522] However, OTFC can induce perioperative emesis and respiratory depression. OTFC has also been introduced for treatment of breakthrough cancer pain.[523] OTFC may be ideally suited to treat breakthrough cancer pain because fentanyl is rapidly absorbed from OTFC and patients can easily self-administer OTFC.

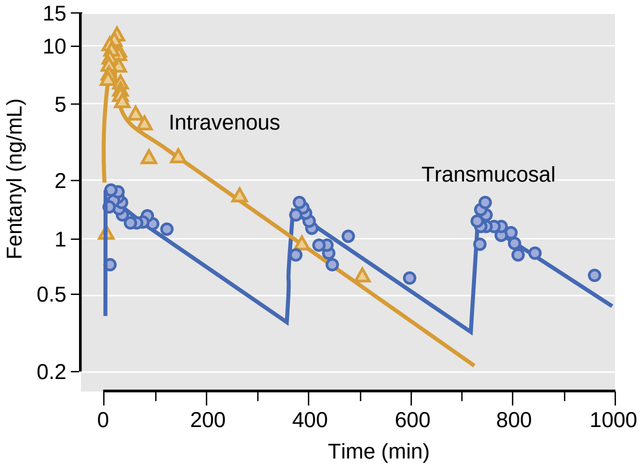

Fig. 24.31 A typical result of time-dependent change in plasma concentration of fentanyl after oral transmucosal fentanyl citrate (OTFC) application and intravenous administration. Three 800-μg doses of OTFC were administered with 6-hour intervals between doses, and fentanyl was infused at a constant rate of 50 μg/minute to a total of 15 μg/kg. (From Egan TD, Sharma A, Ashburn MA, et al. Multiple dose pharmacokinetics of oral transmucosal fentanyl citrate in healthy volunteers. *Anesthesiology*. 2000;92:665–673.)

Delivery of opioids through the nasal mucosa has also been investigated. Side effects of intranasal sufentanil in children include reduced ventilatory compliance (chest wall rigidity), hypoxemia, impaired manual ventilation, nausea, and vomiting.[524] Pharmacokinetic studies in volunteers are reported for fentanyl, alfentanil, sufentanil, butorphanol, oxycodone, and buprenorphine.[525] Mean times for achieving maximum serum concentrations vary from 5 to 50 minutes, while bioavailability varies from 46% to 71%. Fentanyl, pethidine, and butorphanol have been studied for postoperative pain. Mean onset times vary from 12 to 22 minutes and times to peak effect from 24 to 60 minutes. Transnasal butorphanol provides superior and more prolonged analgesia than similar doses given IV for postoperative pain after cesarean section. PCA with intranasal fentanyl was demonstrated to be effective for postoperative pain management.[526] There was no difference in the efficacy of intranasal fentanyl (2 μg/kg), intramuscular morphine (0.1 mg/kg), and intravenous morphine (0.1 mg/kg) in controlling postoperative pain and emergence delirium in children undergoing bilateral myringotomy and placement of ventilating tubes.[527] A novel intranasal morphine formulation composed of morphine monohydrate and chitosan, a nontoxic naturally occurring mucoadherent derived from shellfish, was shown to offer a noninvasive alternative to intravenous morphine for postoperative analgesia in patients after third molar extraction.[528] Intranasal administration of remifentanil (4 μg/kg) produces good intubating conditions in 2 to 3 minutes after induction of anesthesia with sevoflurane in children.[529]

Fentanyl (300 μg) inhalation produces low plasma drug level (0.1 ng/mL) after 15 minutes and analgesia that may be disproportionately greater than expected.[530] Inhaled liposome-encapsulated fentanyl was also demonstrated to be a noninvasive route of administration with a rapid increase and prolonged maintenance of plasma fentanyl concentration.[531] Inhalation of nebulized fentanyl citrate significantly improved patient perception of breathing, respiratory rate, and oxygen saturation in terminally ill cancer patients.[532] This inexpensive and readily available treatment may offer substantial relief of end-of-life dyspnea. The advent of specialized and efficient pulmonary drug delivery systems has facilitated the evaluation of inhaled opioids, such as morphine and fentanyl, for management of severe pain associated with surgery or malignant disease.[533] It was shown that remifentanil delivered by inhalation is rapidly absorbed, pharmacologically active, rapidly cleared, and noninjurious to respiratory tissues in rodents.[534]

The rectal mucosa is another site for transmucosal drug delivery. The bioavailability of 30-mg morphine sulfate controlled-release suppository formulation was significantly greater than that of 30-mg oral controlled-release morphine sulfate tablets, which may be the result of partial avoidance of hepatic biotransformation with rectal administration.[535] The hydrogel formulation of rectal morphine may also be useful for premedication and analgesia in pediatric patients.[536]

Oral Controlled-Release Medications

Despite the high first-pass metabolism of opioid analgesics, morphine has been formulated into an oral, sustained-release tablet (MST) and has been evaluated for premedication, postoperative analgesia, and as an analgesic for chronic cancer pain. MST provides unreliable preoperative anxiolysis and postoperative pain relief, possibly because of delayed time to onset of peak effects (3-5 hours), which can be increased by impaired gastric emptying and absorption from the small intestine. In addition, growing evidence has associated chronic use of sustained release formulation of opioids for noncancer pain to increase the risk of fatal overdose without significant benefit over other non-opioid modalities of analgesia. As an analgesic for chronic cancer pain, MST was shown to be an excellent formula.[537]

The relative analgesic potency of single doses of oral controlled-release oxycodone (20 or 40 mg) and oral controlled-release morphine (45 or 90 mg) was compared in a randomized, double-blind trial in women with moderate-to-severe pain following abdominal hysterectomy.[538] Controlled-release oxycodone at doses of 20 mg or 40 mg was comparable with controlled-release morphine at doses of 45 mg or 90 mg, respectively, for total and peak analgesic effects, indicating that oral controlled-release oxycodone was at least twice as potent as oral controlled-release morphine. A randomized, double-blind, crossover trial indicated that controlled-release oxycodone was as safe and effective as controlled-release morphine in the treatment of cancer pain.[539]

Extended-Release Epidural Morphine (DepoDur)

DepoDur is a novel drug that delivers morphine by using DepoFoam technology, a drug-delivery system composed of multivesicular lipid particles containing nonconcentric aqueous chambers that encapsulate the active drug. When the plasma morphine concentration after epidural administration of 5 mg of standard morphine was compared with those of 5 mg of DepoDur, the terminal half-life was comparable, but the peak concentration was significantly smaller and the peak systemic absorption occurs later with DepoDur. Randomized controlled studies demonstrated that 5-15 mg of DepoDur can be a potentially beneficial analgesic after elective cesarean delivery with no significant increases in adverse events for the period from 24 to 48 hours after surgery.[540,541] When compared to single-shot plain epidural morphine, DepoDur has been shown to provide a longer duration of postoperative pain control, and a decrease in the use of postoperative opioid in lower abdominal surgery,[542] total hip arthroplasty,[543] and total knee arthroplasty.[544] The adverse effect profile of DepoDur is similar to plain epidural morphine and includes nausea, vomiting, pruritus, and hypotension. It was reported that a large dose of epidural lidocaine before DepoDur administration alters the pharmacokinetics and drug effects of DepoDur.[545]

Other Opioid Agonists

CODEINE

Codeine (methylmorphine) is 6-7 fold less potent as morphine, has a high oral-parenteral potency ratio (2:3), and a plasma half-life of 2 to 3 hours. Codeine has mild to moderate analgesic but strong cough-suppressant properties after oral administration. Cytochrome P450 2D6 (CYP2D6) is the enzyme responsible for *O*-demethylation of codeine to morphine, and has genetic variants capable of rapid conversion of codeine to morphine in affected children and adults.[546] IV codeine produces profound hypotension and is neither approved nor recommended.

OXYCODONE

Although oxycodone has been widely used in pain management for more than 90 years, its pharmacokinetic properties are still poorly known. Oxycodone is extensively metabolized in humans mainly by hepatic cytochrome P450, and only 10% of oxycodone is excreted in unchanged form in urine. Rifampin, a strong inducer of several drug-metabolizing enzymes, induces cytochrome P450, reduces the plasma concentration of intravenous and oral oxycodone, and modestly attenuates pharmacologic effects of oxycodone.[547] The role of several metabolites in its analgesic activity is still not fully understood.[548] Oxycodone is a potent analgesic after systemic administration, but its analgesic potency is poor after intrathecal administration.[549] It was shown that oxycodone is more potent than morphine for visceral pain relief in intravenous patient-controlled postoperative analgesia after laparoscopic hysterectomy.[550] With respect to pharmacologic effects other than analgesic effects, it was reported that the extent and speed of onset of oxycodone-induced respiratory depression was dose-dependent and greater than an equivalent dose of morphine.[551]

MEPERIDINE (PETHIDINE)

Meperidine is predominantly a μ-opioid receptor agonist that produces pharmacologic effects similar, but not identical, to those of morphine. Meperidine sometimes causes excitation of the CNS, characterized by tremors, muscle twitches and seizures, that are largely due to accumulation of a metabolite, normeperidine. Meperidine has well-known local anesthetic properties.

Unlike morphine, after intravenous injection, first-pass uptake of meperidine by the lungs is approximately 65%. Meperidine is more highly bound to plasma proteins than is morphine, principally (70%) to α_1-acid glycoprotein. As with morphine, a relatively high hepatic extraction ratio results in biotransformation that depends on hepatic blood flow. The major metabolite normeperidine has analgesic activity and is roughly twice as potent as meperidine in producing seizures in animals. The elimination half-life of normeperidine is considerably greater than that of meperidine, and thus repeated doses can easily produce accumulation of this toxic metabolite in patients with renal disease, with the potential for inducing seizures.

Meperidine is frequently used for postoperative pain management. A comparative study demonstrated that morphine, meperidine, and tramadol resulted in equivalent pain scores in intravenous PCA after abdominal hysterectomy.[552] Meperidine is also used to relieve pain and distress in women in labor. Intravenous meperidine (50 mg) and butorphanol (1 mg) significantly reduced pain intensity 15 minutes after injection in women with moderate to severe labor pain, but the analgesia was often inadequate.[553] Meperidine can be administered as PCA in labor.[554] Meperidine (12.5 to 35 mg) is also effective for prevention and treatment of postoperative shivering.[197,555]

HYDROMORPHONE

Hydromorphone is structurally related to morphine but is approximately 5 to 10 times as potent. Because hydromorphone contains a keto-group in position 6 of the benzol ring, an active 6-glucuronate metabolite is not formed like morphine.[556] However, hydromorphone continues to represent an increased risk under conditions of renal insufficiency and failure due to a reduction in clearance and potential accumulation of hydromorphone-3-glucuronate. A bolus administration of hydromorphone reaches its peak effect in approximately 10-20 minutes, whereas an equivalent morphine bolus will require 20 minutes to reach peak. Analgesia after hydromorphone lasts 4 to 5 hours. Hydromorphone has been used for both acute and chronic pain conditions in adults and children.[557] It was reported that hydromorphone PCA provided adequate postoperative analgesia in gynecological surgery patients and there was no systematic difference between morphine and hydromorphone in opioid-related side effects.[558]

LEVORPHANOL

Levorphanol is the only available semisynthetic opioid agonist of the morphinan series with a long half-life. It is 5 times as potent as morphine with an IM/oral potency ratio of 1:2. Levorphanol may have particular utility in patients with chronic pain and who demonstrate morphine tolerance, perhaps because of differences in opioid receptor activity. Analgesia produced by levorphanol is mediated via its interactions with μ-, δ-, and κ-opioid receptors. Levorphanol is also an NMDA receptor antagonist. The long half-life of the drug increases the potential for drug accumulation.[559]

METHADONE

Methadone is a potent μ-opioid receptor agonist, with the longest half-life among the clinically used opioids. By virtue of one of methadone's isomers, it also exerts an inhibitory effect on NMDA receptors, which are implicated in the development of opioid tolerance, hyperalgesia, and chronic pain. Furthermore, methadone inhibits the reuptake of serotonin and norepinephrine, which may play a role in antinociception and mood elevation. Methadone itself is associated with less abuse potential than either morphine or heroin, and treatment with methadone has been considered to be the "gold standard" by which medication-assisted treatment (MAT) approaches are measured, as part of a comprehensive treatment program for OUD.

Methadone (IV) has an equivalent potency but longer duration of action than morphine. The plasma half-life of methadone is very long and variable (13-100 hours). Despite this property, many patients require dosing every 4 to 8 hours to maintain analgesic effects. Its major clinical applications are in the prevention of opioid withdrawal symptoms and in the treatment of chronic pain. It was shown that the same dose of IV methadone (20 mg) that is effective for postoperative pain is also suitable for the induction of anesthesia in combination with etomidate, and that methadone may have the potential for producing histamine release.[560] In patients undergoing posterior spinal fusion surgery, methadone 0.2 mg/kg at the start of surgery reduced postoperative opioid requirements, decreased pain scores, and improved patient satisfaction.[561] However, perioperative use of methadone represents a major clinical challenge, given the tremendous interpatient half-life variability which could contribute to unexpected postoperative respiratory depression.

OXYMORPHONE

Oxymorphone is a semisynthetic opioid agonist that is specific for the μ-opioid receptor and approved to treat both acute and chronic pain. Due to extensive liver metabolism, oral oxymorphone is contraindicated in patients with moderate-to-severe hepatic impairment.[562] Oxymorphone, structurally related to morphine, is almost 10 times as potent, but has a similar duration of action. It was shown that in patients with acute moderate-to-severe postsurgical pain, oral immediate-release oxymorphone 10, 20, or 30 mg provided significant dose-related pain relief compared with placebo, and this relief was maintained over several days with a safety profile comparable to that of immediate-release oxycodone.[563]

PIRITRAMIDE

Piritramide, a synthetic opioid structurally related to meperidine acting on the μ-opioid receptor, is often used for postoperative analgesia in several Eupropean[564] countries. Lack of hemodynamic effects and less side effects reported in early work made piritramide more suitable for postoperative pain control compared with other potent opioids.

Its relative analgesic potency compared with morphine is approximately 0.7. Intramuscular bolus injections of 7.5 to 15 mg were considered to be adequate for approximately 4 to 6 hours.[564] Pharmacokinetic analysis showed that piritramide is distributed extensively and eliminated slowly, and recommended for intermittent bolus administration.[565] A randomized controlled trial showed that intravenous PCA with piritramide can produce pain management as satisfactory as oral oxycodone after cesarean section.[566] It was also demonstrated that piritramide is at least as effective and as well tolerated as morphine for postoperative analgesia via a PCA system after hysterectomy.[567]

TRAMADOL

Tramadol is a prodrug that is metabolized by CYP2D6 and CYP3A4 to its more potent opioid analgesic metabolites, particularly the *O*-demethylation product M1. There is a significant variability in the efficiency and amount of CYP2D6 enzymes among individuals. Therefore, the large phenotypic variation affects the speed of metabolism and the rate of accumulation or elimination of tramadol.[568]

The action of tramadol to induce analgesia represents the combination of two predominant mechanisms, reuptake inhibition of the noradrenergic serotonergic system and activation of the μ-opioid receptor and to a lesser extent the δ- and κ-opioid receptors.[569] It was suggested that tramadol may also have a direct serotonin-releasing action.[570] Given the analgesic effect of tramadol is only partially reversed by naloxone, its serotonergic and noradrenergic effects likely represent its predominant analgesic action.

Tramadol is onefifth to onetenth as potent as morphine. In rats, tramadol could reduce MAC of isoflurane in a naloxone-sensitive manner.[571] It was shown that intravenously administered tramadol was effective for postthoracotomy pain relief.[572] Analgesic doses of tramadol may produce less respiratory depression in part because of its non-opioid receptor–mediated actions, and have minimal effects on gastrointestinal motor function.[573] Nevertheless, tramadol used as a sole drug cannot be considered the drug of choice after moderately severe painful surgery. The doses needed to relieve pain in 80% of patients are much larger than the usual dose of 50 to 100 mg.[574]

Tramadol added to lidocaine for intravenous regional anesthesia provided a shorter onset time of sensory block.[575] Tramadol added to 1.5% mepivacaine for brachial plexus block enhances the duration of analgesia in a dose-dependent manner with acceptable side effects.[576] Intraarticular tramadol was also used for management and prevention of pain after arthroscopic knee surgery. It was shown that the intraarticular admixture of tramadol 100 mg with 0.25% bupivacaine provides a pronounced prolongation of analgesia compared with either drug alone in patients undergoing arthroscopic knee surgery.[577]

Tramadol has dose- and time-dependent bactericidal activity against *Escherichia coli* and *Staphylococcus epidermidis*, as well as antibacterial activity against *Staphylococcus aureus* and *Pseudomonas aeruginosa*. The antibacterial properties of tramadol might be useful for reduction of bacterial infection after regional anesthesia.[578]

Coadministration of tramadol with proserotonergic medications can result in a hyperserotonergic state, serotonin syndrome, which can be subacute or chronic, and range from mild to severe. In mild cases, patients are afebrile and may report symptoms of diarrhea, tremor, tachycardia, shivering, diaphoresis, or mydriasis.[579] In severe cases, neuromuscular hyperactivity, autonomic hyperactivity, altered mental state, gastrointestinal symptoms, and even death have been reported. Serotonergic medications that can interact with tramadol include selective serotonin reuptake inhibitors, serotonin-norepinephrine reuptake inhibitors, tricyclic antidepressants, triptans (e.g., sumatriptan), antipsychotics, anticonvulsants, antiparkinsonian agents, cough and cold medications containing dextromethorphan, herbal products containing St. John’s wort, and medications that inhibit the metabolism of serotonin, such as monoamine oxidase inhibitors. Because symptoms of serotonergic and norepinephrine withdrawal are possible upon abrupt cessation of tramadol, gradual tapering or symptomatic support are necessary when tramadol administration is stopped.[568]

MORPHINE-6-GLUCURONIDE

Morphine-6-glucuronide (M6G) is a potent metabolite of morphine. In contrast to morphine, M6G is not metabolized but excreted via the kidneys and exhibits enterohepatic cycling, as it is a substrate for multidrug resistance transporter proteins in the liver and intestines.[580] M6G exhibits a delay in its analgesic effect (blood–effect-site equilibration half-life 4-8 hours), which is partly related to slow passage through the blood-brain barrier and distribution within the brain compartment. M6G can be used as an analgesic in humans. Osborne et al. reported that 0.5 to 4 mg IV of M6G was effective for cancer pain for 2 to 24 hours without nausea and vomiting.[581] M6G 100 μg and 125 μg given intrathecally provided excellent analgesia after total hip replacement, as did intrathecal morphine sulfate 500 μg.[582] In a randomized double-blind study it was shown that M6G has an analgesic effect similar to that of morphine over the first 24 hours postoperatively. However, initial onset of M6G effect may be slower than morphine.[583] M6G has also paradoxically been observed to increase pain sensitivity in mice and humans. The pronociceptive effect of M6G can be shown in knockout mice lacking μ-, κ-, and δ-opioid receptors, and might be due to activation of the NMDA receptors.[584]

Agonist-Antagonist Opioid Compounds

Nalorphine, the first agonist-antagonist opioid, was successfully synthesized by Weijland and Erickson in 1942 and was found to be strongly antagonistic to almost all the properties of morphine. Although nalorphine was found to possess strong analgesic actions, it was unsuitable for clinical uses because of its psychotomimetic effects. Nalorphine was used in lower doses as an opioid antagonist.

Agonist-antagonist opioids are usually produced by alkylation of the piperidine nitrogen and addition of a three-carbon side chain such as a propyl, allyl, or methyl allyl to morphine. Buprenorphine is a partial agonist at the μ-receptor and an antagonist at the κ-receptor.

The other compounds are μ-antagonists and full or partial agonists at the κ-receptors. Agonist-antagonist opioids are less prone (but not immune) to abuse because they have analgesic ceiling effects, cause less euphoria, and are associated with less drug-seeking behavior and physical dependence.

Dosing data of these compounds are shown in Table 24.10. The agonist-antagonists compounds depress respiration similarly as morphine, but ceiling effects exist (Table 24.11). Effects on the cardiovascular system differ among these compounds (Table 24.12).

TABLE 24.10 Dosing Data for Agonist-Antagonist Opioids and Morphine

	Equianalgesic IM Dose (mg)	Duration of Analgesia (h)	Oral: IM Efficacy Ratio
Morphine	10	4-5	1:6
Buprenorphine	0.3-0.4	>6	1:2*
Butorphanol	2	3-4	—
Nalbuphine	10	3-6	1:4-5
Pentazocine	40	3	1:3

*Sublingual:IM ratio.
IM, Intramuscular.

TABLE 24.11 Respiratory Depressant Effects of Agonist-Antagonists Compared With Morphine*

Drug	Correlation of Respiratory Depression with Dose
Morphine	Increases proportionally with dose
Buprenorphine	Ceiling effect at 0.15-1.2 mg in adults
Butorphanol	Ceiling effect at 30-60 μg/kg
Nalbuphine	Ceiling effect at 30 mg in adults
Pentazocine	Ceiling effect suggested, but difficult to study because of psychotomimetic effects

*Low or moderate naloxone doses readily reverse the respiratory depressant effects produced by therapeutic doses of all drugs listed, except buprenorphine.

PENTAZOCINE

Analgesia produced by pentazocine is primarily related to κ-receptor stimulation. Pentazocine is onehalf to onefourth as potent as morphine. Ceilings to both analgesia and respiratory depression occur after 30 to 70 mg of pentazocine. Although the potential for abuse is less than with morphine, prolonged use of pentazocine can lead to physical dependence. Nalorphine-like dysphoric side effects are common, especially after high doses (>60 mg) of pentazocine in the elderly. The dysphoric effects of pentazocine can be reversed with naloxone. Pentazocine depresses myocardial contractility and increases arterial blood pressure, heart rate, systemic vascular resistance, pulmonary artery pressure, and left ventricular work index. Pentazocine also increases blood catecholamine levels. Pentazocine inhibits gastric emptying and gastrointestinal transit in rats, whereas U50488H, a pure κ-agonist, did not significantly inhibit either.[585] Therefore, it might be speculated that pentazocine affects gastrointestinal function through a mechanism other than the opioid receptors.

Pentazocine has been shown to be an effective treatment for pruritus after cesarean delivery under spinal anesthesia with opioids, the incidence of which is ranging from 50% to 100%. A single 15-mg dose of IV pentazocine after delivery was shown to reduce both the incidence and severity of pruritus in women who have received subarachnoid opioids during cesarean delivery.[586] Pentazocine has limited application, because it is associated with a high incidence of PONV, it provides limited analgesia, it partially antagonizes other opioids, and it can produce undesirable cardiovascular and psychotomimetic effects.

BUTORPHANOL

Butorphanol is an agonist at κ-receptors. Its activity at μ-receptors is either antagonistic or partially agonistic. It is 5 to 8 times as potent as morphine and is only available in parenteral form. After IM injection, onset of effect is rapid, and peak analgesia occurs within 1 hour. Whereas duration of action of butorphanol is similar to that of morphine, its plasma half-life is only 2 to 3 hours. Although butorphanol (10 mg IM) causes as much respiratory depression as the same dose of morphine, higher doses reach a ceiling. Side effects after butorphanol include drowsiness, sweating, nausea, and CNS stimulation. In healthy volunteers, butorphanol (0.03 or 0.06 mg/kg IV) produces no or minimal cardiovascular changes. However, in patients with cardiac disease, butorphanol causes significant increases in cardiac index, left ventricular end-diastolic pressure, and pulmonary artery pressure.

Because butorphanol decreases the MAC for enflurane by only a small fraction, it cannot serve like the fentanyl congeners as an anesthetic agent. Butorphanol is subject to less abuse and has less addictive potential than morphine or fentanyl. Acute biliary spasm can occur after butorphanol, but increases in biliary pressure are less than after equipotent doses of fentanyl or morphine. Transnasal butorphanol is effective in relieving migraine and postoperative pain.[587]

BUPRENORPHINE

Buprenorphine is a thebaine derivative, μ-receptor partial agonist, and similar in structure to morphine but approximately 33 times more potent. Whereas fentanyl dissociates rapidly from μ-receptors (half-life of 6.8 minutes), buprenorphine has a higher affinity and takes much longer (half-life of 166 minutes) to dissociate. Onset of action of buprenorphine is slow, its peak effect may not occur until 3 hours, and duration of effect is prolonged (<10 hours). Volume of distribution of buprenorphine is 2.8 L/kg and its clearance is 20 mL/kg/min. Plasma concentrations of the metabolites of buprenorphine, norbuprenorphine, buprenorphine-3-glucuronide, and norbuprenorphine-3-glucuronide may approximate or exceed those of the parent drug. Both glucuronide metabolites are biologically active and may contribute to the overall pharmacology of buprenorphine.[588]

Subjective effects (e.g., euphoria) of buprenorphine are similar to morphine. Buprenorphine produces depression of minute ventilation which leveled off at doses higher than 3.0 μg/kg to about 50% of baseline, in contrast to the case of fentanyl, in which dose-dependent respiratory depression results in apnea at doses higher than 2.9 μg/kg (Fig. 24.32).[589] Buprenorphine has been successfully used for premedication (0.3 mg IM), as the analgesic component in balanced anesthesia (4.5-12 μg/kg), and for postoperative pain control (0.3 mg IM). Buprenorphine, like the other agonist-antagonist compounds, is not acceptable as a sole anesthetic, and its receptor kinetic profile restricts its usefulness if other μ-agonists are used. Opioid withdrawal symptoms develop slowly (5-10 days) after buprenorphine is discontinued following long-term use.

A sublingual combination tablet composed of buprenorphine and naloxone in a fixed 4:1 ratio may provide pain relief in patients with chronic pain with OUD. However, the unique pharmacological profile of buprenorphine/naloxone confers it to be a weak analgesic relative to full μ-receptor agonists. Studies investigating the efficacy of buprenorphine/naloxone or buprenorphine alone for the management of non-malignant pain are ongoing. Possible mechanisms of pain relief by buprenorphine/naloxone therapy in opioid-dependent patients with chronic pain may include reversal of opioid-induced hyperalgesia and improvement in opioid tolerance and OUD.[590]

Acute administration of κ-opioid receptor agonists and antagonists has been shown to produce effects characterized as prodepressive or antidepressant, respectively, in rodent behavioral tests, encouraging further investigation of κ-opioid receptor antagonists as potential antidepressant treatments in humans.[591] In a preliminary clinical study, low doses of buprenorphine, which possess κ-receptor antagonist activity, produced impressive alleviation of depressive symptoms in patients that were considered treatment-resistant within 1 week of initiating administration.[592]

NALBUPHINE

Nalbuphine is an agonist-antagonist opioid that is structurally related to oxymorphone and naloxone, and binds to μ-receptors as well as to κ- and δ-receptors. Nalbuphine acts as an antagonist at the μ-receptor and an agonist at the κ-receptor. Activation of supraspinal and spinal κ-receptors results in limited analgesia, respiratory depression, and sedation. Nalbuphine, like other agonist-antagonist compounds, interferes with the analgesia produced by pure μ-agonists. In rats, coadministration of nalbuphine with morphine dose-dependently blocked the development of morphine tolerance and dependence, without attenuation of antinociceptive effect of morphine.[593] Nalbuphine is only available for parenteral use. Onset of effects is rapid (5-10 minutes), and duration is long (3-6 hours) because of a long plasma elimination half-life (5 hours).

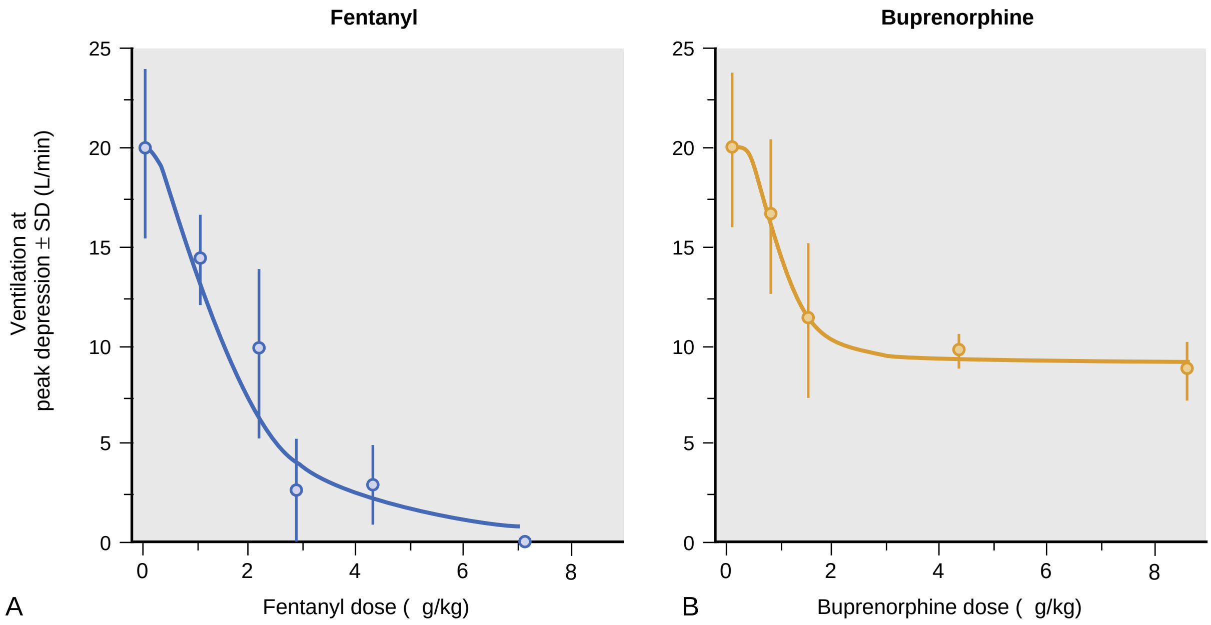

Fig. 24.32 Dose–response relationships for reduction of minute ventilation induced by fentanyl (A) and buprenorphine (B). The response is the peak ventilatory depression at each dose. The *line through the data* is the fit to the Hill equation. Placebo is 0 μg/kg. Data are mean ± standard deviation. (From Dahan A, Yassen A, Bijl H, et al. Comparison of the respiratory effects of intravenous buprenorphine and fentanyl in humans and rats. *Br J Anaesth*. 2005;94:825–834.)

Nalbuphine has been administered as an analgesic supplement for conscious sedation or balanced anesthesia, and as an analgesic for postoperative and chronic pain problems. In patients undergoing myocardial revascularization, continuous infusion of nalbuphine (0.05-0.1 mg/kg/min) and fentanyl (0.15-0.3 μg/kg/min) was compared.[594] It was shown that nalbuphine lacks the ability to attenuate cardiovascular and hormonal responses to tracheal intubation and surgical procedures, and was concluded that continuous infusion of nalbuphine cannot be recommended for anesthesia in patients undergoing myocardial revascularization. For postoperative patient-controlled epidural analgesia, the combination of hydromorphone 0.075 mg/mL and nalbuphine 0.04 mg/mL resulted in lower incidence of nausea and decreased need of bladder catheterization compared with hydromorphone alone.[595] A randomized double-blind controlled study in patients undergoing gynecological operations demonstrated that interaction between morphine and nalbuphine in intravenous PCA admixture is additive, and combination of the two drugs can decrease the incidence of pruritus.[596]

A prospective randomized double-blinded study demonstrated that nalbuphine (4 mg IV) was as effective as ondansetron (4-8 mg IV) for prevention of intrathecal morphine-induced pruritus after cesarean delivery.[597] Some reports showed that nalbuphine provides a rapid and potent antishivering effect similarly as meperidine.[598] However, a quantitative systematic review of randomized controlled trials did not support the conclusion.[197]

DEZOCINE

Dezocine is slightly more potent and acts faster than morphine, with a similar duration. Although no longer used clinically in Western countries, dezocine is gaining popularity in China as an alternative medication for perioperative pain management. A pharmacologic study showed the unique molecular pharmacologic profile of dezocine as a partial μ-receptor agonist, a κ-receptor antagonist, and a norepinephrine and serotonin reuptake inhibitor (*via* norepinephrine transporter and serotonin transporter).[368] Although dezocine was shown to be an effective alternative to fentanyl when administered during outpatient laparoscopy with propofol and N_2O, dezocine was associated with a high incidence of postoperative nausea and a delayed discharge time.[599] In adult patients who had arthroscopic surgery under general anesthesia, dezocine (5 mg IV) and morphine (5 mg IV) were similarly effective for postoperative analgesia and showed similar side effects.[600] A recent report showed that intravenous dezocine 0.1 mg/kg can effectively suppress cough induced by 5 μg/kg fentanyl.[601]

MEPTAZINOL

Meptazinol has been reported to cause minimal respiratory depression because of its selectivity for μ_1-receptors. In patients receiving meptazinol (2.5 mg/kg) with a barbiturate, no cardiovascular changes were observed at tracheal intubation, whereas blood pressure and heart rate were significantly increased in patients receiving fentanyl (5 μg/kg).[602] Side effects (nausea and vomiting) limit its use to relieve severe pain.

Opioid Antagonists

NALOXONE

Clinically, opioid antagonists are used to restore spontaneous ventilation in patients who breathe inadequately after opioid overdoses or opioid anesthesia. In addition, opioid antagonists can reduce or reverse opioid-induced nausea and vomiting, pruritus, urinary retention, rigidity, and biliary spasm associated with numerous therapies employing opioids, such as neuraxial analgesic techniques. It was reported that the potency ratio for naloxone:nalbuphine for antagonism of pruritic effects of epidural morphine was approximately 40:1.[603]

Morphine requirements were significantly less in patients receiving naloxone, suggesting that naloxone enhanced analgesia.[604] Proposed possible mechanisms for this apparent paradoxic effect of naloxone include enhanced release of endogenous opioids and opioid receptor upregulation.

Although naloxone is generally considered to be a pure opioid receptor antagonist, it delays gastric emptying of saline or milk, as does morphine in the rat.[360] Furthermore, high-dose naloxone possesses partial agonistic activity on the μ- and κ-opioid receptors in the cultured cells.[605]

Reversal of Respiratory Depression by Naloxone

In the early 1950s, nalorphine and levallorphan were evaluated as opioid antagonists. They were often found unacceptable because of a high incidence of side effects, as well as incomplete reversal. Naloxone was introduced into clinical practice in the late 1960s. There have been reports of side effects (increases in heart rate and blood pressure) and more serious complications (e.g., pulmonary edema). Initial naloxone dose recommendations ranged from 0.4 to 0.8 mg. Onset of action of IV naloxone is rapid (1-2 minutes), and half-life and duration of effect are short, approximately 30 to 60 minutes. If IV access is not available, naloxone, in doses similar to those given IV, is effectively absorbed after intratracheal administration. Reversal with naloxone is limited by high affinity for and slow dissociation from the μ-opioid receptor of buprenorphine, and depends on the buprenorphine dose and the correct naloxone dose window (Fig. 24.33).[606] Because respiratory depression from buprenorphine may outlast the effects of naloxone boluses or short infusions, a continuous infusion of naloxone may be required to maintain reversal of respiratory depression.[606]

Several mechanisms produce increases in arterial blood pressure, heart rate, and other significant hemodynamic alterations after naloxone reversal of opioids. These include pain, rapid awakening, and sympathetic activation not necessarily due to pain. When patients receiving naloxone for opioid agonist reversal are hypothermic due to intraoperative heat loss, O_2 consumption and minute ventilation can increase two- to threefold.[607] Such metabolic demands also stress the cardiovascular system, increasing cardiac output. In addition, greater degrees of hypercapnia at the time of opioid antagonism will result in greater degrees of cardiovascular stimulation because of associated sympathetic stimulation. Opioid reversal may be particularly hazardous in patients with pheochromocytoma or chromaffin tissue tumors. However, it was also reported that

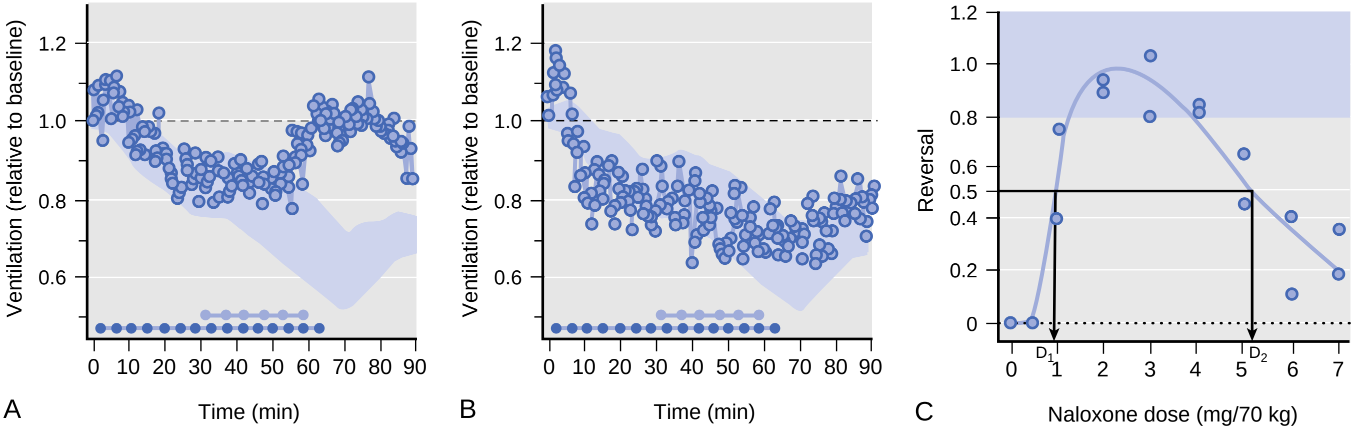

Fig. 24.33 Reversal of buprenorphine-induced respiratory depression with naloxone depends on the correct naloxone dose window. Respiratory depression induced by 0.2 mg buprenorphine was reversed by naloxone 2 mg (A) and 6 mg (B) given over 30 minutes in one subject. Gray field in the background is the result of the placebo group in which saline was infused instead of naloxone. Light gray dots and dark gray dots represent buprenorphine and naloxone infusion, respectively. (C) Influence of 0 (placebo) and 0.5-7 mg naloxone on 0.2 mg intravenous buprenorphine-induced respiratory depression. Reversal was calculated from the naloxone-induced change in ventilation, and it ranges from 0 (effect not different from placebo) to 1 (reversal to predrug baseline level). (From van Dorp E, Yassen A, Sarton E, et al. Naloxone reversal of buprenorphine-induced respiratory depression. *Anesthesiology*. 2006;105:51–57.)

IV administration of 10 mg naloxone did not significantly change plasma catecholamine concentration and blood pressure in pheochromocytoma patients.[608]

Recurrence of respiratory depression after naloxone is due to the short half-life of naloxone. “Renarcotization” occurs more frequently after the use of naloxone to reverse longer-acting opioids such as morphine. This is commonly not seen in clinical practice because opioid concentrations are often just above the threshold for respiratory depression, and treatment with a single or just a few effective bolus doses of naloxone is sufficient to reverse the respiratory depression induced by most opioids for the short time that the agonist concentration exceeds the respiratory depression threshold.[251] Short-acting opioids such as alfentanil rarely pose a danger of renarcotization, because of a rapid plasma decay curve and weak opioid receptor binding compared with fentanyl and sufentanil. Naloxone, although active at μ-, δ-, and κ-receptors, has greatest affinity for μ-receptors, which mediate most potent opioid effects, including respiratory depression and analgesia. Careful titration of naloxone often can restore adequate spontaneous ventilation without reversal of adequate analgesia.

Other Applications of Naloxone

Low-dose naloxone not only has been shown to block the development of acute opioid tolerance but also to ameliorate undesired opioid-induced side effects. Naloxone infusion 0.25 μg/kg/h prevented the acute opioid tolerance induced by a large dose of remifentanil at 0.30 μg/kg/min, provided a quicker recovery of bowel function, and reduced the length of hospital stay after open colorectal surgery.[609]

Reversal of effects of alcohol, barbiturates, and benzodiazepines by naloxone has been reported. However, it was also reported that naloxone potentiates anxiolytic-like action of benzodiazepines and barbiturates in the rat.[610] It is not advisable to try to reverse the effects of overdose of benzodiazepines and barbiturates by naloxone. Although it was suggested that the μ-opioid receptor is involved in the antinociceptive action of ketamine in mice,[74] naloxone did not affect the action of ketamine on secondary hyperalgesia induced by burn injury in humans.[611]

Evidence indicates that endogenous opioid peptides participate in the control of cardiovascular regulation during hemorrhagic shock. In patients with documented septic shock and resistance to a one-liter fluid challenge, administration of naloxone by initial bolus of 0.03 mg/kg followed by infusion at a rate of 0.2 mg/kg/h significantly increased mean arterial pressure, but did not affect survival.[612] This effect may be due to centrally mediated increases in sympathetic tone and decreases in parasympathetic output and/or antagonism of endogenous opioids. However, the clinical usefulness of naloxone to treat shock remains to be determined and additional randomized clinical trials are needed to assess its usefulness.[613]

One study indicated that opioids can elicit excitatory as well as inhibitory modulation of the action potentials of sensory neurons, and ultra-low doses of naloxone could selectively block the excitatory effect of opioids.[614] A prospective randomized double-blind study demonstrated that addition of an ultra-low dose of naloxone (100 ng) to 34 mL of 1.5% lidocaine solution with or without fentanyl in axillary brachial plexus block prolongs the time to first postoperative pain and motor blockade but also lengthens the onset time.[615]

It has been reported that naloxone may ameliorate the neurologic deficit following an ischemic or traumatic neurologic insult in animals.[616] In humans, a randomized controlled trial demonstrated that naloxone (a bolus of 5.4 mg/kg, followed by infusion at 4.0 mg/kg/h for 23 hours) does not improve neurologic recovery after acute spinal cord injury.[617] However, it was reported that combined use of cerebrospinal fluid drainage and naloxone reduces the risk of paraplegia in thoracoabdominal aneurysm repair.[618] Naloxone may also have a therapeutic role in heat stroke disorders[619] and cholestasis-induced pruritus.[620] Although intravenous naloxone has been claimed to produce pain relief in opioid-resistant central post-stroke pain, a double-blind trial concluded that intravenous naloxone was of no value in alleviating central post-stroke pain.[621]

NALTREXONE

Naltrexone is a μ-, δ-, and κ-opioid receptor antagonist. It is longer acting than naloxone (plasma half-life of 8-12 vs. 0.5-1.5 hours), and it is active when taken orally. A double-blind, placebo-controlled study for patients undergoing cesarean section indicated that naltrexone (6 mg) was an effective oral prophylactic against the pruritus and vomiting associated with intrathecal morphine, but was associated with shorter duration of analgesia.[622]

As a prescribed treatment for opioid dependence, extended-release naltrexone hydrochloride was compared directly with opioid medication treatment, which includes daily buprenorphine hydrochloride with naloxone hydrochloride. It was shown that extended-release naltrexone, administered 380 mg as monthly intramuscular injections, was as effective as buprenorphine-naloxone in maintaining short-term abstinence from heroin and other illicit substances and should be considered as a treatment option for opioid-dependent individuals.[343] Importantly, naltrexone induction requires individuals to be completely off opioids due to the likelihood of severe opioid withdrawal.

NALMEFENE

Nalmefene has a greater preference for μ- than δ- or κ-receptors. Nalmefene is equipotent to naloxone. Nalmefene is long-acting after oral (0.5-3.0 mg/kg) and parenteral (0.2-2.0 mg/kg) administration. Bioavailability after oral administration is 40% to 50%, and peak plasma concentrations are reached in 1 to 2 hours. The mean terminal elimination half-life of nalmefene is 8.5 hours, compared with 1 hour for naloxone. Prophylactic administration of nalmefene significantly decreased the need for antiemetics and antipruritic medications in patients receiving intravenous PCA with morphine.[623]

METHYLNALTREXONE

Methylnaltrexone is the first quaternary ammonium opioid receptor antagonist that does not cross the blood-brain barrier.[352] It can reverse adverse effects of opioid medications mediated by peripheral opioid receptors, while the opioid effects mediated by opioid receptors in the central nervous system, such as analgesia, are not affected. Delayed gastric emptying induced by 0.09 mg/kg morphine could be attenuated by 0.3 mg/kg methylnaltrexone in healthy volunteers.[359] Methylnaltrexone has been shown to be effective for management of opioid-induced constipation. It was reported that subcutaneous methylnaltrexone (0.15 mg/kg) rapidly induced laxation in patients who had received opioids for 2 or more weeks and who had received stable doses of opioids and laxatives for 3 or more days without relief of opioid-induced constipation.[624] It was also reported that methylnaltrexone (12 mg once daily) did not affect opioid-mediated analgesia in patients with chronic noncancer pain suffering from opioid-induced constipation who received more than 50 mg of oral morphine equivalents daily.[625] Because methylnaltrexone does not cross the dura, it might have potential to reverse peripherally mediated side effects of epidural opioids.[626] Randomized double-blind placebo-controlled studies have shown effectiveness of methylnaltrexone and alvimopan, another peripherally acting opioid receptor antagonist, in management of postoperative ileus, a transient cessation of coordinate bowel function after surgery.[352]

NALOXEGOL

Methylnaltrexone is restricted by the need for subcutaneous administration and is approved only for treatment of opioid-induced constipation in patients with advanced medical illness. Naloxegol, an oral peripherally acting μ-opioid antagonist, is a pegylated derivative of naloxone. Pegylation confers substrate properties for P-glycoprotein transporter and thus limits the ability of naloxegol to cross the blood–brain barrier. A double-blind study in outpatients with noncancer pain and opioid-induced constipation demonstrated that a daily dose of 12.5 mg or 25 mg naloxegol improved bowel movement, as compared with placebo, without changing pain scores and daily opioid dose.[627]

Drug Interactions With Opioids

GENERAL PRINCIPLES

Opioids are frequently combined with other anesthetic agents to produce optimal anesthetic conditions. Many drugs concomitantly administered for anesthesia can interact each other. Although some of these interactions are intentionally sought, others are unwanted and adverse. There are three general types of mechanisms of drug interactions—pharmaceutical, pharmacokinetic, and pharmacodynamic.[628]

Pharmaceutical interactions are chemical in nature, as illustrated when an alkaline solution of thiopental and an acidic solution of nondepolarizing muscle relaxants precipitate when simultaneously administered via IV.

Pharmacokinetic interactions occur when the administration of one agent alters the pharmacokinetics or disposition of another. Hemodynamic changes induced by one agent can affect pharmacokinetic behavior of the other agent. Sufentanil, which has a greater hepatic extraction ratio than alfentanil, is more likely to be affected by decreases in hepatic blood flow. Cimetidine can prolong opioid effects by decreasing hepatic blood flow and/or diminishing hepatic metabolism. Opioid plasma levels also increase in the presence of propofol.[629] Decreased opioid metabolism, by the CYP 3A4 isoform of the cytochrome P-450 enzyme responsible for the oxidative metabolism of more than 50 drugs, may also underlie pharmacokinetic interactions. A wide range of chemical compounds, including many drugs, can interact with the cytochrome P-450 system, causing either an increased activity (enzyme induction) or enzyme inhibition (Box 24.5).[628] Alfentanil, but not sufentanil, may have its action prolonged as a result of impaired metabolism in patients receiving erythromycin.[630,631]

Pharmacodynamic interaction between opioids and inhaled anesthetics were assessed with classic MAC reduction evaluations in animals and humans. Although marked synergism between opioids and inhaled anesthetics occurs with analgesic doses of opioids, there is a ceiling effect to MAC reduction by opioids. The pharmacodynamic

BOX 24.5 Drugs That Inhibit or Induce Cytochrome P-450 Enzymes

Inhibitors

- Antibiotics
  - Macrolides
  - Troleandomycin
  - Erythromycin
  - Fluoroquinolones
  - Isoniazid
- Azole antifungal drugs
  - Ketoconazole
  - Itraconazole

  - Diltiazem
  - Verapamil
- Omeprazole
- Cimetidine
- Propofol
- Grapefruit juice
- Inducers
- Barbiturates
- Antiepileptics
  - Carbamazepine
  - Phenytoin
  - Primidone
- Rifampicin
- Dichloralphenazone
- Ethanol
- Tobacco smoke

From Bovill JG. Adverse drug interactions in anesthesia. *J Clin Anesth.* 1997;9(Supp):3S.

synergism between opioids and sedative-hypnotics such as propofol is profound. Choosing an opioid with a short context-sensitive half-life allows greater doses of that opioid to be administered, along with reduced doses of propofol, without compromising the time for recovery from anesthesia. Thus, the optimal plasma level of propofol is estimated to be approximately 30% less when it is combined with remifentanil instead of alfentanil.[629]

Drug dosing regimens and plasma concentration of opioid and sedative-hypnotics to provide optimal hemodynamic control during a range of noxious stimuli are necessary. However, complicating our understanding of drug interactions is the observation that the same degree of interaction does not apply across different types of stimuli.

SEDATIVE-HYPNOTICS

Benzodiazepines

Alfentanil was found to reduce the midazolam ED50 value for the induction of anesthesia in a dose-dependent fashion. On the contrary, concerning the antinociceptive effect, interaction between these two types of drugs may be less than additive.[632] Midazolam enhanced opioid-induced antinociception at the spinal level but inhibited it at the supraspinal level.[633] Many studies reveal benzodiazepine-opioid interactions for many properties other than analgesia to be synergistic (supra-additive). Both the cardiovascular and respiratory actions of opioids can be significantly altered by the concomitant administration of benzodiazepines.[634] In anesthetized rabbits, fentanyl and midazolam synergistically caused depression of phrenic nerve activity.[635] Combinations of benzodiazepines and opioids, although occasionally preserving ventricular function, can cause significant and occasionally profound decreases in blood pressure, cardiac index, heart rates, and systemic vascular resistances. Fluid loading may attenuate circulatory depression that occurs when benzodiazepines and opioids are combined.

Barbiturates

Barbiturates can potentiate or produce hypotension if a large dose is administered with opioids. Hypotension after barbiturate-opioid combination is due to venodilatation, decreased cardiac filling, myocardial depression, and decreased sympathetic nervous system activity. Reducing induction doses of barbiturates administered concomitantly with opioids is recommended.

Propofol

Administration of propofol-opioid combinations provides unconsciousness and block responses to noxious stimuli. However, when given as an intravenous bolus for induction of anesthesia, propofol can create moderate to severe preintubation hypotension. Propofol-fentanyl and propofol-sufentanil anesthesia for coronary artery bypass surgery may provide acceptable conditions, but mean arterial pressure can decrease to levels that may jeopardize coronary perfusion, especially during the induction of anesthesia. In healthy volunteers, addition of alfentanil (effect-site concentration of 50 or 100 ng/mL) did not affect the changes in the BIS induced by propofol, but blocked BIS increase induced by painful stimuli.[636] In patients undergoing spine fusion, infusion of fentanyl (blood levels at 1.5-4.5 ng/mL) reduced the infusion rate of propofol necessary to keep mean arterial pressure, but delayed spontaneous eye opening and recovery of orientation.[475] In patients undergoing ambulatory gynecologic laparoscopy, administration of fentanyl (25-50 μg IV) at the time of anesthetic induction reduced maintenance propofol requirement, but failed to provide effective postoperative analgesia and increased the need of postoperative use of antiemetics.[637] Pharmacokinetic interaction as well as pharmacodynamic interaction between propofol and opioids has been reported. Target-controlled infusion of alfentanil (target concentration, 80 ng/ml) was shown to increase blood propofol concentration by 17%, and decrease the elimination clearance, the distribution clearance, and the peripheral volume of distribution of propofol.[638]

Etomidate

Etomidate can be combined in low doses with opioids with little loss of cardiovascular stability. In patients scheduled for coronary artery bypass grafting, etomidate (0.25 mg/kg) plus fentanyl (6 μg/kg) resulted in less hypotension after induction and intubation than propofol (1 mg/kg) plus fentanyl (6 μg/kg).[639]

Ketamine

Many studies on combinations of opioids and ketamine, an NMDA receptor antagonist, have been reported to optimize analgesic therapy to a variety of painful conditions. OIH and subsequent opioid tolerance can be prevented by ketamine in rats, suggesting the usefulness of combination of ketamine and opioids for postoperative analgesia. A pharmacologic study suggested that endogenous opioids and μ- and δ-opioid receptors are also involved in ketamine-induced central antinociception but the κ-opioid receptor is not involved in this effect.[640]

In the acute perioperative setting, results vary depending on the clinical context. Combination of ketamine (2.5 or 10 mg IV) and alfentanil (0.25 or 1 mg IV) provided no advantage over a larger dose of either drug alone in relieving pain caused by intradermal capsaicin injection in healthy volunteers.[641] Furthermore, combination of ketamine 1 mg/mL and morphine 1 mg/mL for PCA did not provide benefit to patients undergoing major abdominal surgery.[642] In contrast, Lauretti et al. reported that oral ketamine and transdermal nitroglycerine effectively reduced daily consumption of oral morphine in patients with cancer pain.[643] A prospective randomized double-blind controlled study demonstrated that intraoperative and postoperative administration of ketamine for the first 48 hours after surgery (2 μg/kg/min after a 0.5 mg/kg bolus) improved postoperative analgesia with a significant decrease of morphine consumption.[644] Furthermore, it was reported that a small dose of ketamine and memantine, a long-acting oral NMDA receptor antagonist, was effective in managing intractable pain in an opioid-tolerant patient.[645] Webb et al. reported that small-dose ketamine could be a useful addition to perioperative tramadol administration in patients undergoing abdominal surgery.[646]

INHALED ANESTHETICS

Volatile anesthetics are frequently combined with opioids in order to ensure amnesia and to promote immobility and hemodynamic stability. Clinical trials of opioids supplemented with volatile anesthetics for cardiac surgery demonstrate well-preserved cardiac output and minimal decreases in mean arterial blood pressure.[647] Myocardial ischemia may not, however, always be ameliorated by approaches that combine opioids with potent inhaled agents in spite of apparent “good” hemodynamic control. Some of the potent inhaled anesthetics can increase sympathetic nervous system activity and may increase the risk of myocardial ischemia in the cardiac patient.[648] Prior administration of fentanyl, in doses as low as 1.5 μg/kg, can markedly attenuate such responses. Alfentanil (10 μg/kg) is also effective in attenuating these effects.

MUSCLE RELAXANTS

Pancuronium bromide has been frequently used for muscle relaxation during high-dose opioid anesthesia. The vagolytic action of pancuronium can attenuate opioid-induced bradycardia and support blood pressure. In patients undergoing coronary artery bypass grafting administered with sufentanil (3-8 μg/kg), pancuronium (120 μg/kg) caused significant increase in mean arterial pressure, heart rate, and cardiac output but did not induce myocardial ischemia.[649] Pancuronium-induced tachycardia was easily and rapidly treated and caused no differences in ischemia or perioperative myocardial infarction. Many factors alter the impact of pancuronium and other muscle relaxants on hemodynamics when combined with opioids: the dose, timing, and rate of administration of each relaxant as well as the premedication, intravascular volume, left ventricular function, and presence of other drugs with autonomic nervous system actions.

Combinations of vecuronium and high doses of opioids may produce negative chronotropic and inotropic effects resulting in decreases in heart rate, cardiac output, and blood pressure, and increases in the need for vasopressor support. In patients scheduled for coronary artery surgery administered with 40 μg/kg sufentanil in combination with vecuronium (0.1 mg/kg), heart rate, mean arterial pressure, and systemic vascular resistance decreased from baseline values after tracheal intubation with neither significant change in cardiac output nor evidence of new myocardial ischemia.[650]

In patients anesthetized with fentanyl 50 μg/kg and scheduled to undergo elective coronary artery bypass grafting, rocuronium 0.6 mg/kg (approximately equivalent to 2 × ED_{95} dose) was associated with changes of only small magnitude in hemodynamic variables, including increases in stroke volume index (+15%) and cardiac index (+11%), and a decrease in pulmonary capillary wedge pressure (−25%).[651] In patients undergoing coronary artery bypass surgery under fentanyl anesthesia, mivacurium 0.15 or 0.2 mg/kg produced decreases in mean arterial pressure and systemic vascular resistance index possibly mediated by histamine release, whereas atracurium (0.5 mg/kg) produced no significant hemodynamic changes.[652]

MONOAMINE OXIDASE INHIBITORS

MAOI can underlie the most serious and potentially fatal drug interaction with opioids. Combination of meperidine and MAOI can induce the serotonin syndrome which is caused by excess serotonin availability in the CNS at the 5-HT_{1A} receptor and characterized by confusion, fever, shivering, diaphoresis, ataxia, hyperreflexia, myoclonus, or diarrhea. The phenylpiperidine series opioids, including meperidine, tramadol, and methadone, appear to be weak serotonin reuptake inhibitors and have all been involved in serotonin toxicity reactions with MAOIs, whereas morphine, codeine, oxycodone, and buprenorphine are known not to be serotonin reuptake inhibitors, and do not precipitate serotonin toxicity with MAOIs.[653] Alfentanil and remifentanil could be used with MAOIs without complications.[654,655]

CALCIUM CHANNEL BLOCKERS

Because opioids can inhibit voltage-dependent Ca^{2+} channel activity through the activation of G proteins, it may be possible that opioid action is potentiated by Ca^{2+} channel blockers. Numerous animal studies and a few clinical studies have documented that opioid-induced analgesia is potentiated by L-type Ca^{2+} channel blockers. However, there is also a report that L-type Ca^{2+} channel blockers do not potentiate morphine analgesia at clinically relevant doses.[656] N-type Ca^{2+} channels are involved in the release of neurotransmitters from sensory neurons in the spinal cord. It was reported that intrathecal administration of a blocker of this channel, ω-conotoxin GVIA, produced antinociception, and interacts synergistically with opioids at the spinal cord level.[657]

MAGNESIUM

Magnesium has been shown to have antinociceptive effects probably due to its antagonistic action on the NMDA receptor. Intravenous administration of magnesium sulfate 50 mg/kg preoperatively and 8 mg/kg/h intraoperatively significantly reduced intra- and postoperative fentanyl requirement.[658] However, passage of magnesium across the blood-brain barrier is limited. Intrathecal administration of fentanyl 25 μg plus magnesium sulfate 50 mg provided significantly prolonged analgesia compared with fentanyl alone, in patients requesting analgesia for labor.[659] It is likely that magnesium can potentiate opioid analgesia by both central and peripheral mechanisms.[660] A randomized, double-blind, prospective study showed that a relatively high dose of remifentanil (0.2 μg/kg/min) enhances periincisional hyperalgesia in patients undergoing thyroidectomy, and intraoperative magnesium sulfate (30 mg/kg at induction followed by 10 mg/kg/h) can prevent remifentanil-induced hyperalgesia.[226]

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs such as ibuprofen, diclofenac, or ketorolac have been perioperatively administered to reduce opioid requirement. It was reported that perioperative administration of diclofenac (75 mg twice daily) reduced morphine consumption and the incidence of adverse effects such as sedation and nausea after total abdominal hysterectomy.[661] In a randomized double-blind trial, 0.1 mg/kg morphine was shown to be superior to 30 mg ketorolac as postoperative pain relief, but adding ketorolac to morphine reduces postoperative opioid requirement and opioid-related side effects in the early postoperative period.[662] Through the reduction of opioid requirements, NSAIDs are thought to help prevent opioid-induced hyperalgesia and/or the development of acute opioid tolerance although direct NSAID-dependent mechanisms are under investigation. A randomized double-blind placebo-controlled study has shown that 8 mg of lornoxicam prevented increase in postoperative morphine consumption induced by intraoperative fentanyl in female patients undergoing abdominal hysterectomy with spinal anesthesia.[663]

ACETAMINOPHEN

Acetaminophen has central analgesic and antipyretic effects that share similarity to those of NSAIDs, but has weak peripheral antiinflammatory action. Acetaminophen has been shown to have significant fentanyl-sparing effects and to reduce side effects when combined with fentanyl in intravenous parent- or nurse-controlled analgesia for postoperative pediatric pain management.[664] On the other hand, a randomized, placebo-controlled, double-blind study in children who received standard propofol-remifentanil anesthesia undergoing spine surgery showed that intravenously administered acetaminophen 90 mg/kg/day did improve analgesia, but did not diminish oxycodone consumption during 24 hours.[665]

GABAPENTINOIDS

Gabapentinoids, such as gabapentin and pregabalin, structural analogs of γ-aminobutyric acid, bind to the $\alpha_2\delta$ subunit of spinal voltage-gated calcium channel, and produce antihyperalgesic effects in neuropathic and other painful conditions. It was suggested that both pharmacodynamic and pharmacokinetic interaction between morphine and gabapentin leads to increased analgesic effects.[666] Furthermore, intrathecal administration of gabapentin was shown to prevent the development of opioid tolerance induced by repeated intrathecal injection of morphine.[667] It might be possible that systemic and intrathecal application of gabapentin prevents the development of OIH.[668] Preoperative administration of pregabalin is proposed as a promising way of enhancing postoperative pain control. A randomized, triple-blinded, placebo-controlled study demonstrated that preoperative administration of 300 mg pregabalin in patients undergoing transperitoneal nephrectomy reduces postoperative opioid consumption and decreases the area of mechanical hyperalgesia.[669]

ANTIDEPRESSANTS

Antidepressants are widely used to treat various chronic inflammatory and neuropathic pain conditions. Results in clinical studies were not consistent with respect to interactions between opioids and antidepressants. An isobolographic analysis demonstrated that systemic amitriptyline and morphine synergistically inhibit cutaneous orofacial inflammatory pain in rats.[670] Tricyclic antidepressants may cause respiratory depression in patients with chronic obstructive pulmonary diseases, and reduced CO_2 sensitivity has also been reported in patients receiving tricyclic antidepressants. An animal study demonstrated that pretreatment with amitriptyline increases morphine-induced hypercarbia through pharmacodynamic processes, suggesting that morphine doses should be reduced with careful titration, if patients are receiving concomitant treatment with tricyclic antidepressants.[671] It was demonstrated that perioperative administration of duloxetine, a potent selective serotonin and norepinephrine reuptake inhibitor, can reduce morphine requirement after knee replacement surgery.[672]

DIPHENHYDRAMINE

Diphenhydramine, a histamine H_1 receptor antagonist, is used as a sedative, an antipruritic, and an antiemetic agent. When administered alone, it modestly stimulates ventilation by augmenting the interaction of hypoxic and hypercarbic ventilatory drives. It was shown that diphenhydramine counteracts the alfentanil-induced decrease in the slope of the ventilatory response to CO_2.[673]

LOCAL ANESTHETICS

Systemic administration of local anesthetics can significantly reduce pain and perioperative systemic lidocaine can significantly reduce opioid requirements.[674] Curiously, previous evidence suggests that opioid-tolerant patients are less responsive to local anesthetics for postoperative pain management. In a study examining the effect of systemic morphine (seven daily subcutaneous injections of morphine 10 mg/kg) on the potency of lidocaine-induced block of the compound action potential in isolated rat sciatic nerves, it was shown that lidocaine potency was decreased due to the intrinsic changes in the peripheral nerve, and the loss of lidocaine potency remained 35 days after the last morphine injection.[675] Because there may be a decrease in potency of local anesthetics even in patients on moderate doses of opioids, additional study is necessary to better guide the perioperative use of systemic lidocaine.

25 Nonopioid Pain Medications

LUCY LIN CHEN and JIANREN MAO

KEY POINTS

- With a better understanding of pain pathways and mechanisms, it has been recognized that ion channels play an important role in the transduction, transmission, and modulation of nociceptive signals. This opens a new avenue of developing novel therapeutic agents for the treatment of acute or chronic pain, particularly neuropathic pain.
- Although the exact mechanism of action remains unclear for many drugs listed in this chapter, they often are a component of a multidrug treatment strategy that has been increasingly used for the management of chronic pain conditions.

Introduction

Recent advances in our understanding of pain mechanisms have enabled us to treat acute and chronic pain conditions with a variety of nonopioid pain medications. The option of using nonopioid pain medications is particularly meaningful given the growing global concern over prescription opioid abuse and overdose. Besides acetaminophen and nonsteroidal antiinflammatory drugs (NSAIDs), several new categories of nonopioid pain medications can be used for the management of acute or chronic pain and, in particular, neuropathic pain. Examples of these nonopioid pain medications include drugs that block voltage-sensitive sodium channels and voltage-sensitive calcium channels, facilitate opening of chloride channels, increase function of the endogenous γ-aminobutyric acid (GABA) system, and modulate the N-methyl-D-aspartate (NMDA) receptor activity. In particular, ion channel blockers possess the antihyperalgesic effect by targeting specific mechanisms of pathologic pain, although most analgesics in this category do not necessarily produce the typical analgesic effect (i.e., raising the pain threshold above the normal baseline).[1]

This chapter briefly discusses NSAIDs and acetaminophen and focuses on describing several ion channel blockers that are commonly used in the treatment of pain conditions, as listed in Box 25.1. They are grouped into two categories: calcium channel blockers and sodium channel blockers.

Nonsteroidal antiinflammatory drugs

NSAIDs include ibuprofen, naproxen, indomethacin, ketorolac, and diclofenac and are examples of a class of medication commonly used as analgesic to reduce myofascial pain, postoperative pain, and chronic pain conditions. In a recent Cochrane review of 16 randomized, controlled clinical trials (2144 patients), pain relief and function restoration were compared in patients with acute soft tissue injury treated with oral NSAIDs and other oral analgesics including acetaminophen with or without opioids. The analgesic effect was similar between NSAIDs and acetaminophen or opioid, and there were no differences in functional restoration at 7 days,[2] but the patients who were taking opioids reported more adverse side effects.[3] Although acetaminophen, indomethacin, or diclofenac produced similar pain reduction, the combination of acetaminophen and diclofenac showed slightly better pain reduction.[4] Intravenous ketorolac (15 or 30 mg) is a common medication of choice during the early postoperative period if there are no contraindications, such as renal insufficiency.[5] Ketorolac has also been successfully used in pediatric surgical patients.[6,7] A recent metaanalysis also found that NSAIDs were equivalent to opioids or paracetamol in the relief of acute renal colic pain.[8]

The cyclooxygenase-2 (COX-2) inhibitors are considered an alternative to NSAIDs (mixed COX-1/COX-2 inhibitors) while possessing reduced gastrointestinal side effects. However, COX-2 inhibition is associated with increased risk of adverse cardiovascular events, although recent clinical studies, including the data from the PRECISION trial that examined long-term cardiovascular safety issues, support the notion that both NSAIDs and COX-2 carry a certain degree of cardiovascular risk.[9]

Acetaminophen

For many decades, oral acetaminophen has been widely used as an analgesic to treat mild to moderate pain. Recently, intravenous acetaminophen has become available in the United States. Results of a randomized trial of patients who had colorectal surgery indicated that

BOX 25.1 Ion Channel Blockers as Pain Medications (Recommended Dosing)

Calcium Channel Blockers

Gabapentin: Starting dose 100–300 mg/day; titrating up to 1800–3600 mg/day
Pregabalin: Starting dose: 75–150 mg/day; titrating up to 450–600 mg/day
Zonisamide: Starting dose: 50–100 mg/day; titrating up to 450 mg/day
Ziconotide: Starting dose: 0.1 μg/h; titrating up to 0.4 μg/h
Levetiracetam: Starting dose: 250–500 mg/day; titrating up to 2000 mg/day

Sodium Channel Blockers

Lidocaine: Used in a lidocaine test: 1 mg/kg via slow intravenous push or drip
Mexiletine: Starting dose: 150–300 mg/day; titrating up to 600 mg/day
Carbamazepine: Starting dose: 100 mg/day; titrating up to 600 mg/day
Oxcarbazepine: Starting dose: 150 mg/day; titrating up to 900 mg/day
Lamotrigine: Starting dose: 25–50 mg/day; titrating up to 250–500 mg/day
Topiramate: Starting dose: 50–100 mg/day; titrating up to 300–400 mg/day.

intravenous acetaminophen decreased postoperative opioid consumption, reduced hospital stay, improved pain control, shortened time to return of bowel function, and lowered the rate of postoperative ileus.[10] Similar results were found after procedures for posterior spinal fusion,[11] craniotomy,[12] vitrectomy,[13] esophagectomy,[14,15] and total joint arthroplasty.[16]

Compared with an opioids-only option for postoperative pain management in adolescents with idiopathic scoliosis, patients treated with intravenous acetaminophen plus ketorolac consumed less opioids and had less severe constipation.[17] A retrospective analysis of the results of the Premier Database of 61,017 cholecystectomy patients showed that 31,133 (51%) of the patients who received intravenous acetaminophen had experienced a shorter length of hospital stay, a decrease in hospitalization costs, a reduced average daily morphine-equivalent dose, and lower rates of respiratory depression, nausea, and vomiting.[18] However, several studies have failed to show that intravenous acetaminophen achieved the positive results as described here.[19-21] The hepatic side effect is a significant concern for those with long-term acetaminophen use, particularly with alcohol. A recent analysis of nine prospective cohort studies has also linked long-term acetaminophen use with an increased risk of adverse neurodevelopmental outcomes following prenatal acetaminophen exposure.[22]

Calcium Channel Blockers

Opening of calcium channels is an important step of synaptic transmission because it facilitates release of neurotransmitters and neuromodulators from presynaptic sites. Changes in intracellular calcium concentration also modulate cell membrane excitability and initiate a cascade of intracellular responses. Therefore blocking calcium channels can play a significant role in modulating both nociceptive and antinociceptive processes. Drugs that reduce calcium influx into the intracellular compartment of neuronal or glial cells may be used as adjunctive or alternative medications for the treatment of various pain conditions, particularly chronic neuropathic pain conditions. Most calcium channel blockers used as antihypertensive drugs may be suitable for chronic pain management because of their side effects and site of action. Gabapentin, pregabalin, zonisamide, ziconotide, and levetiracetam are examples of drugs that block calcium channels as a part of their mechanisms of action and have been used in pain management.

GABAPENTIN

Gabapentin was initially approved by the U.S. Food and Drug Administration (FDA) as an anticonvulsant (partial seizure) and is currently extensively used for the treatment of neuropathic pain conditions. Although gabapentin's mechanism of action is unclear, it does block voltage-gated calcium channels by binding to the α_2-δ subunit,[23] thereby reducing calcium influx. By blocking calcium influx, gabapentin reduces the release of glutamate and substance P from primary nociceptive afferents, thereby modulating nociceptive transmission. Gabapentin has been used to treat painful diabetic neuropathy, postherpetic neuralgia, trigeminal neuralgia, complex regional pain syndrome, and painful peripheral neuropathies caused by human immunodeficiency virus (HIV), cancer, multiple sclerosis, and spinal cord injury.

Painful diabetic neuropathy is a debilitating condition commonly seen in patients with diabetes mellitus. Up to 25% of patients with diabetes may suffer from spontaneous pain, allodynia, hyperalgesia, paresthesias, and other pain symptoms.[24] Postherpetic neuralgia is another common neuropathic pain condition. The incidence of postherpetic neuralgia is estimated to be 9% to 34%, which increases significantly with age. Multiple classes of drugs have been tried to treat pain associated with painful diabetic neuralgia and postherpetic neuralgia, including tricyclic antidepressants (TCAs) such as amitriptyline, nortriptyline, imipramine, and desipramine. Because of the significant side effects of TCAs, gabapentin has been increasingly used in the treatment of these pain conditions.

Gabapentin is effective in reducing several salient symptoms of neuropathic pain such as burning and shooting pain, allodynia, and hyperalgesia.[25,26] The number needed to achieve at least 50% pain relief with antidepressants and gabapentin are 3.4 and 2.7, respectively.[27] Although both antidepressants and gabapentin may provide moderate pain relief, antidepressants may have more major side effects.

The recommended gabapentin dose range is 1800 to 3600 mg/day, starting at 100 to 300 mg/day and increasing 100 to 300 mg every 1 to 3 days. Adverse effects are usually mild to moderate and typically subside within 7 to 10 days after the treatment is started; however, serious side effects can occur including mood swing, edema, and suicidality. In general, a slow titration process can significantly reduce some otherwise intolerable side effects, such as dizziness. In addition to its use as a monotherapy, gabapentin has been extensively used in multimodal drug therapy in conjunction with TCAs and other anticonvulsants.[1] Multimodal drug therapy provides better pain control, requiring a smaller dose range for each drug included in the regimen. Gabapentin also can treat complex regional pain syndrome, phantom pain, trigeminal neuralgia, cancer-related neuropathic pain, multiple sclerosis, spinal cord injury, HIV-associated painful sensory neuropathy, and glossopharyngeal neuralgia.

The role of gabapentin in acute postoperative pain management remains unclear.

PREGABALIN

Pregabalin is an anticonvulsant that has a high affinity to the α_2-δ subunit of voltage-sensitive calcium channels. The mechanism of action of pregabalin is similar to that of gabapentin. Pregabalin decreases calcium influx, thereby reducing the release of excitatory neurotransmitters, including glutamate, substance P, and calcitonin gene–related peptide. Pregabalin has no activity on GABA or benzodiazepine receptors; therefore it has no significant drug-drug interactions with such agents.

Pregabalin has been used to treat painful diabetic neuropathy and postherpetic neuralgia, with a significant therapeutic effect.[28,29] It has a quick onset, and, in some cases, pain reduction can be expected on the first day of treatment with pregabalin (300 mg/day). Sustainable sleep improvement is also observed 1 week after the therapy is initiated. Common side effects are dizziness, somnolence, and mild to moderate peripheral edema.[30] Other concerns over pregabalin include behavioral changes such as mood swing and suicidality. Before starting pregabalin, it is recommended to check the baseline creatinine level. Moreover, pregabalin (at an average dose of 450 mg/day) is effective in patients with fibromyalgia, who often have clinical presentations including diffuse musculoskeletal pain, sleep disturbance, and fatigue.

ZONISAMIDE

Zonisamide blocks both voltage-sensitive sodium channels and N-type calcium channels. Studies suggest that zonisamide may be used to treat mania, Parkinson disease, and poststroke central pain or to provide migraine prophylaxis.[31,32] Its possible mechanisms of action include modulation of monoamine neurotransmitter release and free radical scavenging. Zonisamide is effective for the treatment of painful diabetic neuropathy (540 mg/day). The tolerability of zonisamide is difficult to assess because it is often used in multimodal drug therapy. Thus the data on the effectiveness and side effects of zonisamide remain limited.

ZICONOTIDE

Ziconotide is a synthetic peptide analogue of omega conotoxin derived from a marine snail, *Conus magus*. Ziconotide potently and selectively blocks N-type voltage-sensitive calcium channels. This drug is approved only for intrathecal use in patients with severe pain who are refractory to other treatment options, including intrathecal morphine. In early clinical trials, ziconotide exhibited severe central nervous system and psychiatric adverse effects with an initial intrathecal infusion rate of 0.4 μg/h and frequent dosing titration.[33] More recently, ziconotide has been shown to be effective for chronic pain conditions resulting from cancer, acquired immunodeficiency syndrome, and trigeminal neuralgia.[34,35] The role of ziconotide in postoperative pain management is less clear. Given ziconotide's significant side effects and restrictive delivery route, its routine use in acute postoperative pain management is not well justified.

The initial infusion rate of ziconotide should start at 0.1 μg/h intrathecally, with a slow titration of no more than 2 to 3 times the initial dose per week. An implanted intrathecal infusion system is required for the long-term use of this therapy if the initial ziconotide trial is effective.[36] Patients with severe psychiatric disorders may not be proper candidates for this therapy. On the other hand, ziconotide may be advantageous over intrathecal morphine because patients do not develop tolerance after a prolonged use of ziconotide. However, adverse neurologic effects associated with ziconotide therapy will require careful patient selection and monitoring. Using a smaller dose increment may help to avoid systemic toxicity.

LEVETIRACETAM

Levetiracetam is an anticonvulsant approved by the FDA for treatment of epilepsy.[37] Its mechanisms of action are less clear because it may have effects on several neurotransmitter systems, including dopaminergic, glutamatergic, and GABAergic systems. But at least one of its mechanisms of action is due to inhibition of N-type voltage-sensitive calcium channels. Levetiracetam improves neoplastic plexopathies, painful peripheral neuropathy, and postherpetic neuralgia. It also has been used in migraine headache prophylaxis. The dose range is 500 to 2000 mg/day. At this dose range, levetiracetam is well tolerated in clinical trials. Common adverse effects are dry eyes and dizziness.[38]

Sodium Channel Blockers

Sodium channels are primarily involved in nerve conduction. Sodium channels can be divided into two general categories based on their sensitivity to tetrodotoxin (TTX): TTX-sensitive (TTX-S) and TTX-resistant (TTX-R) sodium channels. TTX-S sodium channels are expressed mainly in large and medium dorsal root ganglion neurons, whereas TTX-R sodium channels are expressed mainly in small-diameter dorsal root ganglion neurons, including C-afferent neurons. Expression of both TTX-S and TTX-R sodium channels is likely to be altered when peripheral nerves are injured or severed (axotomy), producing aberrant high-frequency spontaneous ectopic discharges. Sodium channel blockers at a proper dose range are believed to suppress ectopic discharges without blocking normal nerve conduction, which forms the basis of using sodium channel blockers in the treatment of chronic pain conditions, particularly neuropathic pain. Selective Nav 1.7 and Nav 1.8 sodium channel blockers are being investigated for possible clinical applications. Currently, several representative sodium channel blockers include lidocaine, mexiletine, carbamazepine, oxcarbazepine, lamotrigine, and topiramate.[39]

LIDOCAINE

Lidocaine is a local anesthetic and cardiac antiarrhythmic. Since the 1980s, intravenous administration of lidocaine has been used as a diagnostic tool and, in some cases, a therapeutic tool for intractable neuropathic pain.[39] This treatment modality has been shown to improve chronic pain conditions induced by neurologic diseases, including stroke, neurogenic facial pain, and myofascial pain.[40,41] Up to 78% of cases are associated with a positive outcome when intravenous lidocaine is used.[42] A major pitfall of intravenous lidocaine treatment is its short duration, which requires frequent treatment sessions.

Topical 5% lidocaine patch and over-the-counter topical lidocaine gel or cream provide a local analgesic effect with a minimum systemic effect. Lidocaine patch has been used in patients with neuropathic pain conditions such as painful diabetic neuropathy, postherpetic neuralgia, and peripheral neuropathies. It reduces allodynia and hyperalgesia associated with such conditions.[43] Although the evidence remains weak and unclear, lidocaine patch has been used to treat chronic lower back pain. In some cases, lidocaine patch has become a part of multimodal drug therapy, such as a combination of topical lidocaine patch and gabapentin.[1]

MEXILETINE

Mexiletine is an oral lidocaine congener. It may be used to overcome the shortcoming of transient pain relief with intravenous lidocaine. In many cases, intravenous lidocaine is used as a test to determine whether the intended lidocaine treatment is effective. When a positive response is achieved, oral mexiletine is administered to maintain the therapeutic effect.[44,45] This treatment regimen reduces pain due to painful diabetic neuropathy refractory to other therapies.[46] Mexiletine alone has been used to treat phantom pain and pain after spinal cord injury.[46]

Fibromyalgia and myofascial pain are other clinical conditions that may be responsive to a lidocaine and mexiletine treatment regimen. In addition, anecdotal reports suggest that oral mexiletine may be used to treat primary erythromelalgia, metastasis bone pain, and headaches.

CARBAMAZEPINE

A primary mechanism of action of carbamazepine is sodium channel blockade, which decreases spontaneous firing of Aδ-fibers and C-fibers. Carbamazepine has been approved to treat trigeminal neuralgia, a neuropathic pain condition characterized by episodic lightning, lancinating, or shooting pain along the trigeminal nerve distribution.[47] Carbamazepine has been used for decades and was superior to placebo in a number of clinical trials. It was once considered a "gold standard" and remains a treatment of choice for trigeminal neuralgia, with a response rate of 89% within 5 to 14 days after the treatment is initiated. However, carbamazepine has significant drug-drug interactions and a long list of adverse effects, including central nervous system side effects. In the United States the FDA has issued black box warnings about this drug, including aplastic anemia and agranulocytosis. Therefore its clinical utility is rather limited considering that newer anticonvulsants are available with fewer and less severe side effects.

OXCARBAZEPINE

Oxcarbazepine is an analogue of carbamazepine, which acts as a sodium channel blocker and stabilizes neuronal membrane. In contrast to carbamazepine, oxcarbazepine has fewer drug-drug interactions and side effects, particularly severe blood dyscrasias. The most common side effects of oxcarbazepine are dizziness, drowsiness, hypotension, nausea, and asymptomatic mild hyponatremia. Oxcarbazepine has been used to treat intractable trigeminal neuralgia refractory to other anticonvulsants.[48] With a median dose of 750 mg/day, this novel drug appears to have the same efficacy as carbamazepine in the treatment of trigeminal neuralgia but a much lower incidence of side effects.

Oxcarbazepine also reduces pain associated with painful diabetic neuropathy and complex regional pain syndrome. For patients with postherpetic neuralgia that is unresponsive to carbamazepine and gabapentin, oxcarbazepine, starting at 150 mg/day and titrating up to a maintenance dose of 900 mg/day, may be a promising drug because it significantly reduces allodynia related to postherpetic neuralgia. Oxcarbazepine appears to be well tolerated and may serve as a reasonable alternative to other sodium channel blockers.

LAMOTRIGINE

Lamotrigine has multiple mechanisms of action, although it also blocks both sodium and calcium channels.[49] Lamotrigine is effective in the treatment of trigeminal neuralgia, neuralgia after nerve section, and pain related to HIV neuropathy. With a daily lamotrigine dose of 75 to 300 mg, the intensity of burning and shooting pain is relieved by 33% to 100%, and the frequency of shooting pain attack is reduced by 80% to 100%. In patients with spinal cord injury, lamotrigine decreases overall pain sensation to less than the level of injury in patients with incomplete spinal cord injury but has little effect on spontaneous and evoked pain in patients with complete spinal cord injury.

A typical starting dose for lamotrigine is 25 to 50 mg/day, which can be slowly titrated up over 2 to 3 weeks to 250 to 500 mg/day in divided doses. Tolerability is usually low at high doses (>300 mg/day). Up to 10% of patients may have rashes after taking this medication, with a 3 in 1000 incidence of Stevens-Johnson syndrome. Other side effects are mild dizziness, somnolence, nausea, and constipation.

TOPIRAMATE

Topiramate is another drug that has multiple mechanisms of action. However, at least one of its actions is to block voltage-sensitive sodium channels. It also may potentiate GABA inhibitory action, block voltage-sensitive calcium channels, and inhibit subtypes of glutamate receptors (non-NMDA receptors). Topiramate can cause significant weight loss (up to 7%), a side effect that could be beneficial for certain patient populations with chronic pain conditions. Topiramate, at a daily dose of 400 mg or greater, attenuates neuropathic pain, improves sleep quality, and reduces body weight.[48] When used to treat chronic lumbar radicular pain, the effect of topiramate is inconclusive because of a high dropout rate and frequent side effects in clinical trials. However, topiramate 30 to 80 mg/day is superior to placebo for the treatment of chronic tension, migraine, and cluster headaches with a substantial tolerability.[50]

Intravenous Drug Delivery Systems

MICHEL MRF STRUYS, ANTHONY RAY ABSALOM, and
STEVEN L. SHAFER

KEY POINTS

- The pharmacokinetics of anesthetic drugs are described by multicompartment models. Accurate intravenous drug delivery requires adjusting the maintenance infusion rates to take into account the accumulation of the drug in the peripheral tissues.
- *Biophase* is the site of action of a drug. Initiation, maintenance, and titration of intravenous anesthetics must account for the delay in equilibration between plasma and the site of drug effect.
- Some drug effects directly reflect the concentration of the drug in the biophase (direct-effect models). Other drug effects reflect the alteration of feedback systems by anesthetics (indirect-effect models). The influence of opioids on ventilation reflects the dynamic influence of opioids on the feedback between ventilation and carbon dioxide and is thus an example of an indirect drug effect.
- The target concentration in the effect site is the same as the target concentration in plasma at steady state. Effect-site requirements are influenced by patient physiologic characteristics, surgical stimulation, and concurrent drug administration. Ideally, target concentrations should be set for the hypnotic (volatile anesthetic or propofol) and the analgesic (opioid) that properly accounts for the synergy between them.
- To achieve an effective target concentration, the conventional teaching of administering an initial dose as calculated by the product of target concentration and volume of distribution, followed by a maintenance rate as calculated as the product of target concentration and clearance, is inaccurate. The initial dose may be calculated as the product of target concentration and volume of distribution at peak effect. Maintenance rates must initially account for the distribution of drug in peripheral tissues and should only be reduced to the product of target concentration and clearance after equilibration of plasma and peripheral tissue concentrations.
- The terminal half-life does not reflect the clinical time course of drug plasma concentration. The context-sensitive decrement time is the time for a given decrement in drug concentration, as a function of the duration of infusion that maintains a steady plasma concentration. Context-sensitive decrement times properly incorporate the multicompartment behavior of intravenous anesthetics. The context-sensitive half-time is the time for a 50% decrement in concentration.
- Alfentanil, fentanyl, sufentanil, remifentanil, propofol, thiopental, methohexital, etomidate, ketamine, midazolam, and dexmedetomidine can all be administered as a continuous intravenous infusion. Specific caveats, infusion rates, and titration guidelines are presented in this text.
- Target-controlled infusions (TCIs) use pharmacokinetic models to determine intravenous anesthetic administration rates required to achieve specified plasma or effect-site drug concentrations. Various plasma and effect-site targeting TCI systems are commercially available worldwide (except within the United States) to administer hypnotics and opioids.
- Closed-loop drug delivery systems have used the median electroencephalographic frequency, bispectral index (BIS), or auditory-evoked potentials to control intravenous anesthetic delivery. Although these systems have generally performed well clinically, they remain under investigation.

Introduction

Drugs must reach their site of action to be effective. In 1628, William Harvey proved in Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus that venous blood was transported to the arterial circulation and thus to body organs by the heart. That drugs injected into veins could be rapidly carried to the entire body was rapidly recognized. Consequently, for intravenous drug delivery to be successful, predictable intravenous access is essential.

The development of intravenous methods of anesthetic drug delivery has been made possible by technologic advances. In the middle of the 17th century, Christopher Wren and his Oxford contemporaries applied a feather quill and animal bladder to inject drugs into dogs and humans and rendered them unconscious. The hollow hypodermic needle and a functional syringe were developed by Frances Rynd (1801–1861) and Charles Pravaz (1791–1853), respectively. Contemporary needles, catheters, and syringes are descendants of these early devices. In the twentieth century, equipment began to be made of plastics, first polyvinyl chloride, then Teflon, and later, polyurethane. In 1950, Massa invented the Rochester needle (Fig. 26.1),[1] which led to the revolutionary concept of the "over-the-needle" catheter, which is still the gold standard for intravenous access for nearly all intravenous drug delivery today.[2]

Although fundamental principles of intravenously administering drugs were known in the 18th century, intravenous induction of anesthesia became common only in the 1930s after the discovery of barbiturates. Maintenance of anesthesia by intravenously administered anesthetics has become practical, safe, and popular in the past 2 decades. Intravenous drugs such as methohexitone and thiopental, although suitable for intravenous induction of anesthesia, are not suitable for use by infusion for the maintenance of anesthesia. In the case of thiopental, accumulation can lead to cardiovascular instability and delayed recovery, whereas methohexitone is associated with the excitatory phenomenon and epileptiform electroencephalographic (EEG) changes. Although the next generation of intravenous drugs, such as ketamine, althesin, and etomidate, possessed desirable pharmacokinetic characteristics, their use has been limited as a result of other side effects, including hallucinations, anaphylaxis, and adrenal suppression, respectively. The discovery of propofol in 1977 provided the anesthetic practice an intravenous drug suitable for both induction and maintenance of anesthesia; currently, propofol is still one of the most frequently used drugs for this purpose.[3] Other drugs suitable for continuous infusion used today are some of the opioids such as alfentanil and sufentanil and certainly the short-acting opioid remifentanil. In addition, some of the nondepolarizing neuromuscular blocking agents are used as continuous infusions in specific situations.

Drugs are still predominantly injected as a bolus or continuous infusion using standard dosing guidelines, thereby ignoring the large interindividual variability in the dose-response relationship.[4] In contrast to inhaled anesthetics, for which the inspired and end-tidal concentrations can be continuously measured in real time ("online"), the actual plasma or effect organ concentration of an intravenously administered drug is not immediately measurable in clinical practice. Therefore manually adjusting the intravenous drug injection regimens to maintain an online measured plasma concentration is impossible. It becomes even more complex if a specific effect-site concentration is the target. Optimal patient-individual dosing may be achieved by the application of pharmacokinetic-pharmacodynamic principles. Additionally, recent findings suggest that the pharmacokinetic and pharmacodynamic interactions during intravenous administration of various drugs are important and, as such, should be taken into account when optimizing drug administration.[5,6] Computer technology can be used to assist the clinician in titrating intravenous drug administration by using the therapeutic end point as the feedback signal for dosing (Fig. 26.2).

The development of the first mechanical syringe pumps in the 1950s improved the quality of intravenous drug administration. A more recent technologic development in intravenous anesthesia is the introduction of computerized pharmacokinetic model–driven continuous-infusion devices, enabling the attainment of desired plasma levels of an intravenous anesthetic drug by using a computer-controlled infusion pump operated in accordance with the published pharmacokinetics of the drug.[7] These efforts have resulted in the release of the first commercial target-controlled infusion (TCI) device in Europe, developed by Zeneca specifically for the administration of propofol. Since that time, several countries (with the exception of the United States) have approved the use of TCI devices for the delivery of anesthetic drugs.[8]

The ultimate development in anesthetic delivery systems will be devices for closed-loop administration of intravenous drugs during anesthesia. Systems have been developed for closed-loop administration of various drugs such as neuromuscular blocking agents, hypnotics, and opioids. The control variables for these systems have included various pharmacodynamic measures derived from techniques such as acceleromyography, automated blood pressure measurement, and electroencephalography.

The dose-response relationship can be divided into three parts (see Fig. 26.2): (1) the time course of the relationship between the given dose and the plasma concentration is defined as pharmacokinetics, (2) the relationship between the plasma concentration and/or effect-organ concentration and the clinical effect is defined as pharmacodynamics, and (3) the coupling between pharmacokinetics and pharmacodynamics is required when the blood is not the site of drug effect.

Before reviewing delivery techniques and devices for intravenous anesthesia, this chapter presents some pharmacokinetic and pharmacodynamic principles as background for understanding how to administer intravenous drugs to their best advantage. Further discussion of the principles of pharmacokinetics and pharmacodynamics can be found in Chapter 23.

Pharmacokinetic Considerations

The aim of optimal intravenous drug dosing is to reach and maintain a desired time course of therapeutic drug effect as accurately as possible, thereby preventing dose-related adverse drug effects. To be useful in anesthesia, this time course should include a rapid onset of clinical effects, smooth maintenance, and fast recovery after the termination of drug administration. The pharmacokinetics of many intravenous drugs can be described using mammillary multicompartment pharmacokinetic models. These models assume that the drug is directly given and mixed in the plasma, resulting in an immediate peak in its plasma concentration.

The easiest clinical technique is to administer a single dose, calculated to keep the plasma concentration above the therapeutic target concentration for the required time (Fig. 26.3). A constant concentration cannot be maintained, but it should not decrease to less than the therapeutic concentration. Unfortunately, when one single bolus is used, the initial dose must be large enough to maintain a concentration above the lowest therapeutic concentration even at the end of surgery. However, this sometimes very large dose of drug may cause numerous side effects attributable to the initially high concentrations in the body. It might be less harmful to keep the drug concentration above the lowest therapeutic level without very high initial concentrations by repeatedly injecting smaller doses; even with this technique, however, maintaining a stable plasma concentration is still impossible.

To produce a time course of drug effect that follows the time course of anesthetic requirement, a continuous infusion titrated to the perceived anesthetic requirement should be used. Typically, just enough amount of drug is given to achieve the therapeutic blood or plasma drug concentration. Drug administration thereafter should be continuously titrated throughout surgery. Although such a regimen does not overshoot the required concentration (and therefore avoids the risk of concentration-related side effects), yet another difficulty exists. Whereas, the large bolus approach produces an effective concentration (EC) from the onset, albeit with an excessive overshoot, a continuous infusion takes a long time to become effective because of the slow increase in concentration. Reaching steady state (see Fig. 26.3) takes a very long time during which the increase in concentration is rapid at first but then slows down as equilibrium is approached. For example, it will take longer than 1 hour for the propofol infusion to generate a plasma concentration that is at least 95% of the steady-state concentration. Consequently, although simple infusions are obviously very effective for maintaining constant blood concentrations once steady state is reached and for avoiding overshoot, infusions do not offer a clinically realistic approach. Therefore a combination of an initial bolus followed by a stepwise decreasing continuous infusion is more useful.[9,10]

Pharmacokinetic models can be used to calculate the required drug-dosing regimen to reach and maintain a therapeutic drug concentration as fast as possible without overshooting or accumulation. In this chapter, an explanation of how pharmacokinetic models can be used to calculate accurate dosing schemes for use with intravenous drug delivery systems is offered.

Pharmacokinetic models are mathematical descriptions of how the body *disposes* of drugs. The parameters describing this process are estimated by administering a known dose of the drug and measuring the resulting plasma concentrations. A mathematical model then relates the input over time, I(t), with the concentrations over time, C(t). These models can take many forms. Fig. 26.4 shows concentrations in plasma and effect site over time after a single intravenous bolus of drug at time 0. Drug concentrations continuously decrease after the bolus, and the rate of decrease is approximately proportional to the amount of drug in plasma. Typically, this behavior can be described with the use of exponential models. The curve might have a single exponent, in which case the plasma concentrations over time might be described by the function $C(t) = Ae^{-kt}$, where A is the concentration at time 0 and k is a constant that describes the rate of decrease in concentration. The relationship appears to be a straight line when graphed as the log of concentration versus time. The pharmacokinetics

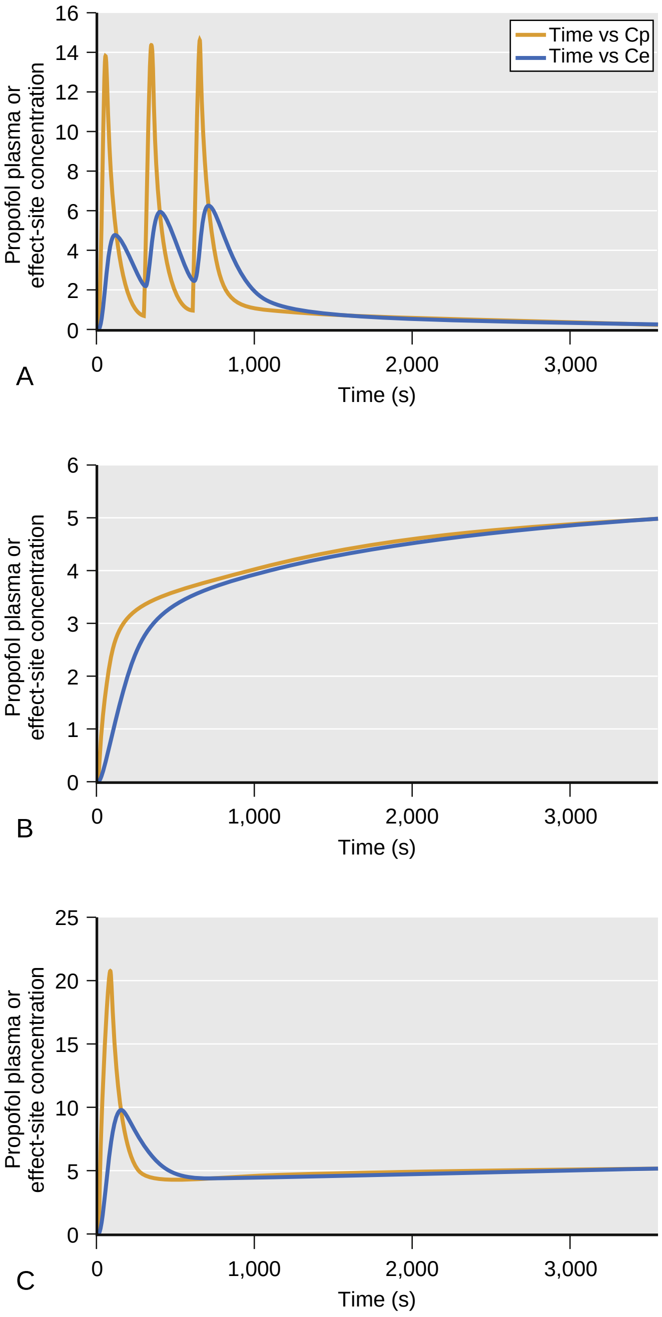

Fig. 26.3 Predicted propofol plasma concentration *(Cp)* and effect-site concentration *(Ce)* for a repeated bolus dose (1 mg/kg given at time 0 and after 5 and 10 minutes) (A), continuous infusion (10 mg/kg/h) (B), and a bolus (2 mg/kg) followed by a continuous infusion (10 mg/kg/h) (C). Simulated patient is a man, 45 years of age, 80 kg, 175 cm; Schnider model.

of intravenous anesthetic drugs is more complex because after the bolus, a period of rapid decline is observed before the terminal *log-linear* portion (i.e., the part that is a straight line when described as log concentration vs. time). This process can be modeled by taking several monoexponential curves and adding them together. The result is a polyexponential curve. For example, the concentrations after an intravenous bolus might be described by an equation with two exponents, $C(t) = Ae^{-\alpha t} + Be^{-\beta t}$, or an equation with three exponents, $C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$.

The aforementioned is applied to single bolus dosing, which is, of course, only one way of administering intravenous anesthetic drugs. A more general way to think of pharmacokinetics is to decompose the input into a series of small bits (boluses) and consider each bit of drug separately. The general pharmacokinetic model of drug disposition commonly used in anesthesia independently considers each bit of drug and analyzes its contribution by means of polyexponential decay over time. The formal mathematic description of each bit of drug in terms of polyexponential decay over time is the relationship (Eq. 26.1)

$$C(t) = I(t) * \sum_{i=1}^{n} A_i e^{-\lambda_i t} \tag{26.1}$$

where C(t) is the plasma concentration at time t and I(t) is drug input (i.e., a bolus or infusion). The summation after the asterisk (described later in this chapter) is the function describing how each bit of drug is disposed (hence the name, *disposition function*). Note that this is again a sum of *n* exponentials, as described in the previous paragraph.

Pharmacokinetic modeling is the process of estimating the parameters within this function. The integer *n* is the number of exponentials (i.e., compartments) and is usually two or three. Each exponential term is associated with a coefficient A_i and an exponent λ_i. The λ values are inversely proportional to the half-lives (half-life = ln 2/λ = 0.693/λ), with the smallest λ representing the longest (terminal) half-life. The A values are the relative contribution of each half-life to overall drug disposition. If a drug has a very long terminal half-life but a coefficient that is significantly smaller than the other coefficients, then the long half-life is likely to be clinically meaningless. Conversely, if a drug has a very long half-life with a relatively large coefficient, then the drug will be long lasting even after brief administration. The asterisk (*) operator is the mathematic process called *convolution*, which is simply the process of breaking the infusion into *bits* of drug and then adding up the results to observe the overall concentrations resulting from the disposition of the different bits up to a time point t.

The pharmacokinetic model shown has some useful characteristics that account for its enduring popularity in pharmacokinetic analysis. Most important, the model describes observations from studies reasonably well, the *sine qua non* for models. Second, these models have the useful characteristic of *linearity*. Simply stated, if the dose, I, is doubled (e.g., administering a bolus twice as large or an infusion twice as fast), then the resulting concentrations should be doubled.

More generally, linearity implies that the system (i.e., the body acting to produce a plasma drug concentration output from a drug dosage input) behaves in accordance with the principle of superposition. The superposition principle states that the response of a linear system with multiple inputs can be computed by determining the response to each individual input and then summing the individual responses. In other words, when the body treats each bit of drug by polyexponential decay over time, the *disposing* of each bit of drug does not influence the disposing of other bits of drug.

The third reason for the continuing popularity of these models is that they can be mathematically transformed from the admittedly nonintuitive exponential form shown

Fig. 26.4 Steps involved in pharmacokinetic model–driven infusion. Typically, pharmacokinetic models are derived from experiments in which plasma drug concentrations are measured at intervals after bolus administration of the drug. Nonlinear regression is used to fit a monoexponential, biexponential, or triexponential curve to the resulting concentration-versus-time data. An algebraic relationship exists between the exponential decay curves and a one-, two-, or three-compartment pharmacokinetic model. The bolus-elimination-transfer (BET) infusion scheme is developed and consists of a bolus, a continuous infusion to replace drug eliminated from the body, and an exponentially declining infusion to replace drug transferred out of plasma to other body compartments. BET infusion results in the maintenance of a constant specified plasma drug concentration. Practical implementation of the BET scheme with real infusion pumps and infusion rates that change only at discrete intervals of time results in a plasma drug concentration profile that approximates that resulting from a BET infusion.

earlier to a more intuitive compartment form (Fig. 26.5). The fundamental parameters of the compartment model are the volumes of distribution (central, rapidly equilibrating, and slowly equilibrating peripheral volumes) and clearances (systemic, rapid, and slow intercompartment). The central compartment (V_1) represents a distribution volume and includes the rapidly mixing portion of the blood and first-pass pulmonary uptake. The peripheral compartments are made up of tissues and organs that show a time course and extent of drug accumulation (or dissipation) different from that of the central compartment. In the three-compartment model, the two peripheral compartments may roughly correspond to splanchnic and muscle tissues (rapidly equilibrating) and fat stores (slowly equilibrating). The sum of the compartment volumes is the apparent volume of distribution at steady state (Vd_{ss}) and is the proportionality constant relating the plasma drug concentration at steady state to the total amount of drug in the body. The intercompartment rate constants (k_{12}, k_{21}, and so on) describe the movement of drug between the central and peripheral compartments. The elimination rate constant (k_{10}) encompasses processes acting through biotransformation or elimination that irreversibly removes drug from the central compartment.

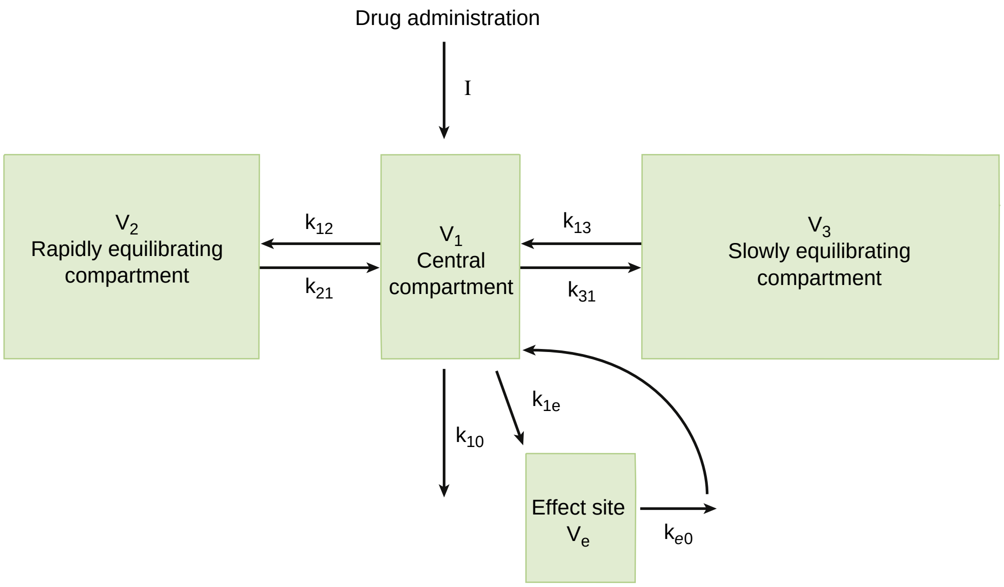

Fig. 26.5 Three-compartment model (including the biophase) illustrating the basic pharmacokinetic processes that occur after intravenous drug administration. *I,* Dosing scheme as a function of time; k_{10}, rate constant reflecting all processes acting to remove drug irreversibly from the central compartment; *k,* intercompartment rate constants; V_1, central compartment volume, usually expressed in liters or liters per kilogram.

Despite their physiologic flavor, compartment models are simply mathematic transformations of the polyexponential disposition functions computed from observed plasma concentrations. Thus physiologic interpretation of volumes and clearances (with the possible exception of systemic clearance and Vd_{ss} [the algebraic sum of the volumes]) is entirely speculative.

The last reason behind the popularity of these models is that they can be used to design infusion regimens. If the disposition function (Eq. 26.2)

$$\sum_{i=1}^{n} A_i e^{-\lambda_i t} \tag{26.2}$$

is abbreviated as simply D(t), then the relationship among concentration, dose, and the pharmacokinetic model D(t) can be rewritten as (Eq. 26.3)

$$C(t) = I(t) * D(t) \tag{26.3}$$

where * is the convolution operator, as noted earlier. In the usual pharmacokinetic study, I(t) is known, the dose that is given the patient, and C(t) is measured, the concentrations over time. The goal is to find D(t), the pharmacokinetic disposition function. Pharmacokinetic analysis can be thought of as a simple rearrangement of Eq. 26.3 to solve for D(t) (Eq. 26.4)

$$D(t) = \underset{I(t)}{\overset{C(t)}{\rightarrow\!\leftarrow}} \tag{26.4}$$

where the symbol $\rightarrow\leftarrow$ means *deconvolution*, the inverse operation of convolution. Deconvolution is similar to division, but of functions rather than simple numbers. When dosing regimens are designed from known pharmacokinetic models and a desired course for the plasma concentration over time, the known values are D(t) (the pharmacokinetics) and $C_T(t)$ (the desired target concentrations), and the drug dosing scheme is (Eq. 26.5)

$$I(t) = \underset{D(t)}{\overset{C_T(t)}{\rightarrow\!\leftarrow}} \tag{26.5}$$

Thus the necessary infusion rates, I(t), can be calculated, given the desired target concentrations, $C_T(t)$, and the pharmacokinetics, D(t), by applying the same tools used to calculate the original pharmacokinetics. Unfortunately, such a solution might require some negative infusion rates, which are obviously impossible. Because a drug cannot be retracted from the body (i.e., give inverse infusions), clinicians must restrict themselves to plasma concentrations over time that can be achieved with noninverse infusion rates.

The standard pharmacokinetic model has one glaring shortcoming. It assumes that after a bolus injection there is complete mixing within the central compartment such that the peak concentration occurs precisely at time 0. It actually takes approximately 30 to 45 seconds for the drug to make its transit from the venous injection site to the arterial circulation. This model misspecification over the first minute or so may not seem significant, but it can cause problems in attempts to relate the drug effect after a bolus to drug concentrations in the body,[11] which becomes even more important when using effect-site TCI.[12] The standard polyexponential pharmacokinetic models are being modified to provide more accurate models of plasma drug concentration in the first minute after bolus injection, also taking into account infusion rate. Recently, Masui and associates[13] found that a pharmacokinetic model consisting of a two-compartment model with a LAG (the time shift of dosing as if the drug were, in fact, administered to the pharmacokinetic model at a later time) and presystemic compartments model accurately described the early pharmacologic phase of propofol during infusion rates between 10 and 160 mg/kg/h. The infusion rate has an influence on kinetics. Age was a covariate for LAG time (Fig. 26.6). Besides compartment models, various physiologically based

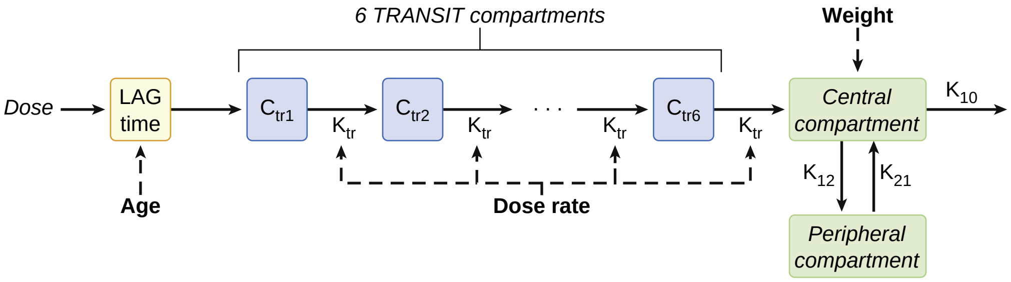

Fig. 26.6 Scheme of the final two-compartment pharmacokinetic model with a LAG time and six TRANSIT compartments (C_{tr} *n*). The equilibration rate constants between the central and peripheral compartments were calculated using the following equations: $k_{12} = Cl_2 \div V_1$, $k_{21} = Cl_2 \div V_2$. The elimination rate constant was calculated using the following equation: $k_{10} = Cl_1 \div V_1$. Cl_1, Clearance of central compartment; Cl_2, clearance of peripheral compartment; V_1, distribution volume of central compartment; V_2, distribution volume of peripheral compartment. LAG time represents the time shift of dosing as if the drug was, in fact, administered to the pharmacokinetic model at a later time. TRANSIT compartments depict a multiple-step process represented by a chain of presystemic compartments. (From Masui K, Kira M, Kazama T, et al. Early phase pharmacokinetics but not pharmacodynamics are influenced by propofol infusion rate. *Anesthesiology.* 2009;111:805–817. Used with permission.)

models have been developed to model the pharmacokinetic behavior of anesthetics.[14] So far, these models are not superior at predicting the time course of drug concentration.[13] None of these models have been used to control intravenous drug delivery devices.

Pharmacodynamic Considerations

THE BIOPHASE

The goal of drug titration during anesthesia is to reach and maintain a stable therapeutic drug concentration at the site of drug effect, also defined as the *effect site* or *biophase*. For most drugs used in anesthesia, the plasma is not the biophase and thus even after the drug has reached the arterial circulation, a further delay occurs before a therapeutic effect is observed. The reason is that additional time is required for the drug to be transported to the target organ, penetrate the tissue, bind to a receptor, and induce intercellular processes that ultimately lead to the onset of drug effect. This delay between peak plasma concentration and peak concentration at the effect site is called *hysteresis*. Fig. 26.7 illustrates an example of hysteresis revealed during an experiment published by Soehle and coworkers.[15] Two periods of continuous propofol infusions were given. The time course of the plasma concentration and effect-site concentration are simulated using pharmacokinetic and pharmacodynamic models. The cerebral drug effect was measured using the EEG-derived bispectral index (BIS). A clear delay between the time course of the plasma concentration and that of the BIS can be observed. The plasma concentration versus effect curve forms a counterclockwise hysteresis loop. This loop represents the plasma concentration, which is not the site of drug effect. Using nonlinear mixed-effect modeling, the hysteresis is minimized to reveal the effect-site concentration versus clinical effect relationship. The typical sigmoidal population model is also depicted in Fig. 26.7.

The concentration of drug in the biophase cannot be measured because it is usually inaccessible, at least in human subjects. The time course of drug effect can be calculated by using rapid measures of drug effect. Knowing the time course of drug effect, the rate of drug flow in and out of the biophase (or effect site) can be calculated with the use of mathematic models. As such, the time course of the plasma concentration and the measured effect can be linked using the concept of the *effect compartment*, developed by Hull[16] and Sheiner.[17] The effect-site concentration is not a real measurable concentration but rather a virtual concentration in a theoretic compartment without a volume and, as such, also without any significant amount of drug present. For any concentration in this virtual compartment, a corresponding assumed effect is observed. This relationship between the effect-site concentration and effect is usually nonlinear and static (i.e., does not explicitly depend on time). If the plasma concentration is maintained at a constant level, then the model assumes that, at equilibrium, the effect-compartment concentration equals the plasma concentration. The delay between the plasma and the effect compartment is mathematically described by a single parameter, defined as k_{e0}, the effect-site equilibration rate constant (see Fig. 26.5).[18]

Measures of drug effect used to characterize the time course of drug transfer between plasma and the biophase vary with the drug being evaluated. For some drugs, a direct measure of drug effect can be applied. For neuromuscular blocking agents, the response from peripheral nerve stimulation (i.e., the twitch) is an ideal measure of effect. Various authors have used the T1% (percentage change of the T1 response compared with baseline T1 response during supramaximal stimulus) derived from electromyogram to measure the drug effect of newer drugs such as rocuronium[19] and cisatracurium.[20] For other categories of drugs such as opioids and hypnotics, the real clinical effects (e.g., unconsciousness, amnesia, memory loss, antinociception) are not measurable. For these reasons, surrogate measures are used to quantify the time course of clinical effects. These surrogate measures can be categorical or continuous. For example, the Observer's Assessment of Alertness/Sedation (OAA/S) scale was used to measure quantal changes in hypnotic drug effects during propofol administration.[21] Egan and colleagues[22] applied a noxious pain stimulus and used an algometer to measure the balance between nociception and antinociception during remifentanil infusion. Various spontaneous and evoked EEG-derived and processed measures were used to measure cerebral drug effects for opioids and hypnotics.[15,23-27] Ludbrook and associates measured propofol concentrations in the carotid artery and

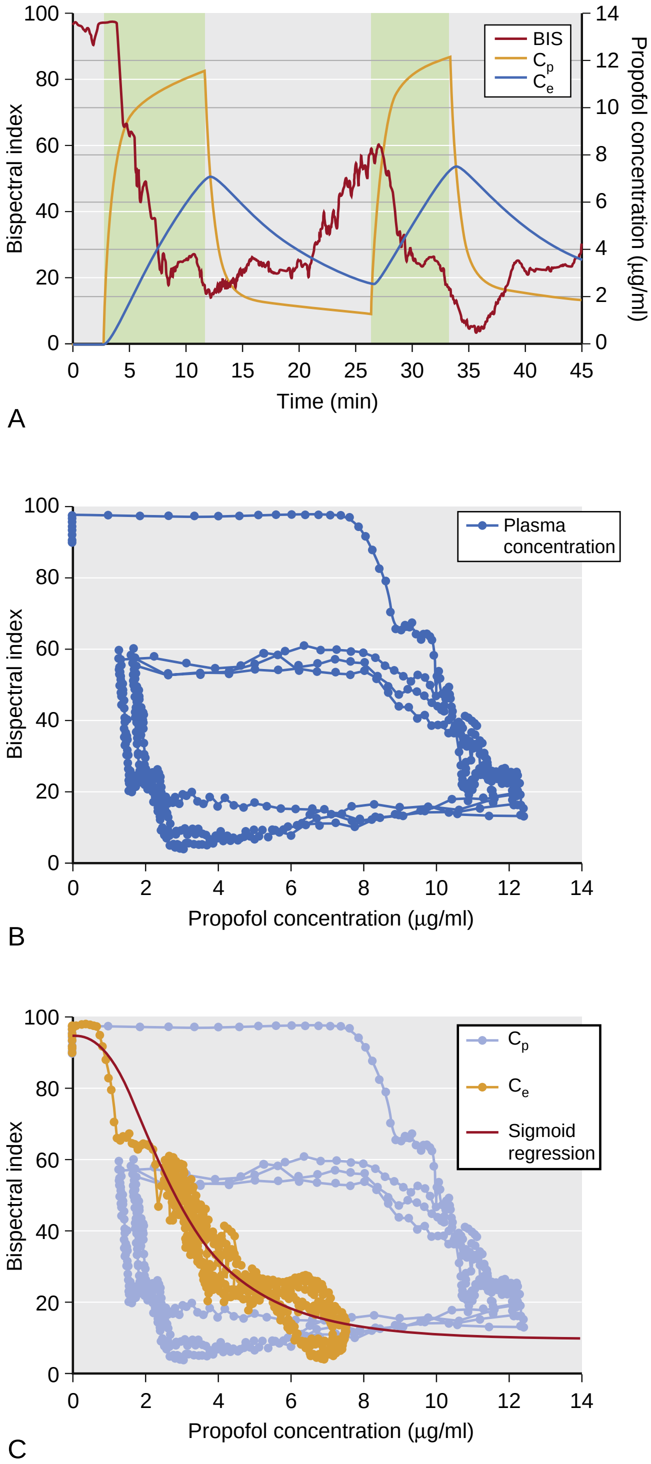

Fig. 26.7 (A) Time course of an experiment showing the hysteresis between plasma concentration *(C_p)* and hypnotic effect as measured by the electroencephalographic (EEG)-derived bispectral index (BIS). Propofol was given at a constant rate during the shaded periods, resulting in C_p *(orange line)* and effect-site concentration *(C_e) (blue line)*. The corresponding BIS values are shown as a *solid red line*. (B) Relation between C_p and BIS using data from the experiment reveals a hysteresis loop. (C) After modeling, this hysteresis is minimized as shown in the relation between the effect-site concentration and BIS. ([A] Modified from Soehle M, Kuech M, Grube M, et al. Patient state index vs bispectral index as measures of the electroencephalographic effects of propofol. *Br J Anaesth.* 2010;105:172–178. Used with permission; [B and C] Courtesy M. Soehle, Bonn, Germany.)

jugular bulb to establish movement of propofol into and equilibration with the brain. They simultaneously measured the BIS and found a close correlation between brain concentration (calculated by mass balance) and changes in the BIS.[28]

DIRECT-EFFECT MODELS

As with plasma pharmacokinetics, the biophase concentration is the convolution of an input function (in this case, the plasma drug concentration over time) and the disposition function of the biophase. This relationship can be expressed as (Eq. 26.6)

$$C_{biophase}(t) = C_{plasma}(t) * D_{biophase}(t) \qquad (26.6)$$

The disposition function of the biophase is typically modeled as a single exponential decay (Eq. 26.7)

$$D_{biophase}(t) = K_{e0} e^{-K_{e0} t} \qquad (26.7)$$

The monoexponential disposition function implies that the effect site is simply an additional compartment in the standard compartment model that is connected to the plasma compartment (see Fig. 26.5). The effect site is the hypothetical compartment that relates the time course of plasma drug concentration to the time course of drug effect, and k_{e0} is the rate constant of elimination of drug from the effect site. By convention, the effect compartment is assumed to receive such small amounts of drug from the central compartment that it has no influence on plasma pharmacokinetics.

Neither $C_{biophase}(t)$ nor $D_{biophase}(t)$ can be directly measured, but the drug effect can be measured. Knowing that the observed drug effect is a function of the drug concentration in the biophase, the drug effect can be predicted as (Eq. 26.8)

$$Effect = f_{PD}\left[C_{plasma}(t) * D_{biophase}(t),\ P_{PD},\ k_{e0}\right] \qquad (26.8)$$

where f_{PD} is a pharmacodynamic model (typically sigmoidal in shape), P_{PD} represents the parameters of the pharmacodynamic model, and k_{e0} is the rate constant for equilibration between plasma and the biophase. Nonlinear regression programs are used to find values of P_{PD} and k_{e0} that best predict the time course of drug effect. This method is called *loop-collapsing* (see Fig. 26.7). Knowledge of these parameters can then be incorporated into dosing regimens that produce the desired time course of drug effect.[29,30]

If a constant plasma concentration is maintained, then the time required for the biophase concentration to reach 50% of the plasma concentration ($t_{1/2}k_{e0}$) can be calculated as $0.693/k_{e0}$. After a bolus dose, the time to peak biophase concentration is a function of both plasma pharmacokinetics and k_{e0}. For drugs with a very rapid decline in plasma concentration after a bolus (e.g., adenosine with a half-life of several seconds), the effect-site concentration peaks within several seconds of the bolus, regardless of k_{e0}. For drugs with a rapid k_{e0} and a slow decrease in concentration after a bolus injection (e.g., pancuronium), the peak effect-site concentration is determined more by k_{e0} than by plasma pharmacokinetics.

An accurate estimation of k_{e0} demands an integrated pharmacokinetic-pharmacodynamic study combining rapid blood sampling with frequent measurements of drug effect, yielding an overall model for the dose-response behavior of the drug. Historically, the time constants of pharmacokinetic models and the k_{e0} of pharmacodynamic studies were sometimes naively merged, possibly leading to inaccurate predictions of the clinical drug effect. Coppens and colleagues proved that pharmacodynamic models of BIS in children developed by using estimates of plasma propofol concentrations from published pharmacokinetic models and estimating the pharmacodynamic model do not ensure good pharmacokinetic accuracy or provide informative estimates for pharmacodynamic parameters.[31] If no integrated pharmacokinetic-pharmacodynamic model exists, then the time to peak effect (t_{peak}) after a bolus injection can be used to recalculate k_{e0} using the pharmacokinetic model of interest to yield the correct time to peak effect. Under these circumstances, this alternative approach might lead to a more accurate prediction of the dose-response time course.[32,33] However, the correct covariates for t_{peak} should be estimated in a specific population.[34] A second caveat is that the time course of drug effect is specific for a given effect (e.g., cerebral drug effect as measured by a specific processed EEG). The time course of other side effects (e.g., hemodynamic effect for hypnotics) most frequently follows a different trajectory.[35,36] The time to peak effect and the $t_{1/2}$ k_{e0} for several intravenous anesthetics are listed in Table 26.1.

All methods discussed so far incorporate k_{e0} values calculated on the assumption that hysteresis between plasma concentration and clinical effect is explained by a delay in drug transfer between plasma and biophase and thus that anesthesia is a smooth, path- and state-independent, symmetric process. Although still commonly used, this assumption might be suboptimal. Data from animal experiments suggest that neural processes and pathways involved in anesthesia induction and recovery are different.[37,38] In an animal study, measured brain drug concentrations at loss of consciousness and at return of consciousness were significantly different.[39] If these data are confirmed, then a more complex model (e.g., one incorporating a second, serial effect-site model) might be required to depict the time course of drug effect. Several groups have investigated this hypothesis in humans, and so far the published findings are not consistent. One clinical study specifically designed to address this topic showed evidence supportive of the concept of neural inertia.[40] Two other studies involving secondary analyses of existing data, of which one indicated supportive evidence[41] and the other showed that neural inertia was not present in all subjects, and appeared to occur only with propofol (and not with sevoflurane), and to be present only with certain pharmacodynamic endpoints.[42]

TABLE 26.1 Time to Peak Effect and $t_{1/2}$ k_{e0} After a Bolus Dose

Drug	Time to Peak Drug Effect (min)*	$t_{1/2}$ k_{e0} (min)
Morphine	19	264
Fentanyl	3.6	4.7
Alfentanil	1.4	0.9
Sufentanil	5.6	3.0
Remifentanil	1.8	1.3
Ketamine	—	3.5
Propofol	1.6	1.7
Thiopental	1.6	1.5
Midazolam	2.8	4.0
Etomidate	2.0	1.5

*Measured by electroencephalography.

k_{e0} is the rate constant for transfer of drug from the site of drug effect to the environment.

$t_{1/2}$ k_{e0} = 0.693/k_{e0}

INDIRECT-EFFECT MODELS

Thus far, clinical effects that are an instantaneous function of drug concentration at the site of drug effect have been discussed, as implied by Eq. 26.8. For example, once a hypnotic drug reaches the brain or a neuromuscular-blocking drug reaches the muscles, drug action is almost immediately observed. On the other hand, some effects are significantly more complex. For example, consider the effect of opioids on ventilation. Initially, opioids depress ventilation, and arterial tension of carbon dioxide (CO_2) gradually accumulates. Yet, the accumulation of CO_2 at normal conditions is a strong stimulant for ventilation, thereby partly counteracting the ventilatory depressant effects of opioids. Ventilatory depression is an example in which direct and indirect drug effects are incorporated. The direct effect of the opioid is to depress ventilation, and the indirect effect is to increase arterial tension of CO_2. Modeling the time course of opioid-induced ventilatory depression requires consideration of both components. Bouillon and colleagues developed a model of ventilatory depression that incorporates both direct and indirect effects.[43-45] As is generally the case with indirect-effect models, characterizing drug-induced ventilatory depression requires a consideration of the entire time course of drug therapy, which is embodied by the following differential equation (Eq. 26.9):

$$\frac{d}{dt}PaCO_2 = k_{e1} \bullet \left[1 - \frac{Cp\,(t)\,\gamma}{C_{50}\gamma + C_p\,(t)\,\gamma}\right]_F \bullet \left[\frac{P_{biophase}\,CO_2\,(t)}{P_{biophase}\,CO_2\,(0)}\right] \bullet PaCO_2\,(t) \qquad (26.9)$$

where partial pressure of arterial carbon dioxide ($Paco_2$) is arterial CO_2, $P_{biophase}CO_2$ is CO_2 in the biophase (i.e., brainstem respiratory control circuits), k_{el} is the rate constant for the elimination of CO_2, C_{50} is the effect-site opioid concentration associated with a 50% reduction in ventilatory drive, and F is the steepness or *gain* of the effect of CO_2 on ventilatory drive.

DOSE IMPLICATIONS OF THE BIOPHASE

The delay in onset of clinical effects has important clinical implications. After a bolus, the plasma concentration peaks nearly instantly and then steadily declines. The effect-site concentration starts at zero and increases over time until it equals the descending plasma concentration. The plasma concentration continues to decline. After the moment of identical concentrations, the gradient between plasma and the biophase favors removal of drug from the biophase, and the effect-site concentration decreases. The rate at which the effect-site concentration rises toward the peak after a bolus dictates how much drug must be injected into plasma to produce a given effect. For alfentanil, its rapid plasma effect-site equilibration (large k_{e0}) causes the effect-site concentration to rise rapidly, with a peak produced in approximately 90 seconds. At the time of the peak, approximately 60% of the alfentanil bolus has been distributed into peripheral tissues or eliminated from the body. For fentanyl, the effect-site concentration rises significantly more slowly and peaks 3 to 4 minutes after the bolus.[46] At the time of the peak, more than 80% of the initial bolus of fentanyl has been distributed into tissues or eliminated. As a result of slower equilibration with the biophase, relatively more fentanyl than alfentanil must be injected into plasma, which makes the rate of offset of drug effect after a fentanyl bolus slower than after an alfentanil bolus.

This difference in pharmacokinetics indicates that k_{e0} must be incorporated into dosing strategies on which rational drug selection is dependent. For rapid onset of effect, a drug with a large k_{e0} (short $t_{1/2}$ k_{e0}) should be chosen. For example, for rapid sequence induction of anesthesia, alfentanil or remifentanil may be the optimal opioid because its peak effect-site concentration coincides with the likely time of endotracheal intubation. However, for a slower induction of anesthesia in which a nondepolarizing neuromuscular blocking agent is used, an opioid with a slower onset of drug effect should be selected to coincide with the peak effect of the neuromuscular blocking agent. In this case, a bolus of fentanyl or sufentanil at the time of induction may be more appropriate. The time to peak effect for the commonly used opioids is shown in Fig. 26.8. Knowing k_{e0} (or time to peak effect) also improves titration of the drug by identifying the time at which the clinician should make an assessment of drug effect. For example, midazolam has a slow time to peak effect, and repeat bolus doses should be spaced at least 3 to 5 minutes apart to avoid inadvertent overdosing.

An accurate k_{e0} is also crucial during TCI titrating to a specific effect-site concentration because the initial bolus given to reach the targeted effect-site concentration depends on both the pharmacokinetics and the k_{e0}.[47]

DRUG POTENCY

Single Drugs

Knowledge about adequate therapeutic drug concentration is crucial to achieve the aim of providing optimal anesthetic conditions. Therefore information on drug potency is essential. Analogous to the concept of minimum alveolar concentration (MAC), the concentration associated with a 50% likelihood of movement in response to skin incision for inhaled anesthetics[48] is the C_{50} for intravenous drugs, which provides a measure of relative potency between intravenous anesthetics.

There are many ways to look upon C_{50}, taking into consideration whether the clinical effect is a binary or continuous effect. When considering binary effects, the C_{50} might be the drug concentration that prevents response (e.g., movement, hypertension, release of catecholamines) to a particular stimulus (e.g., surgical incision, endotracheal intubation, spreading of the sternum) in 50% of patients. In this case, each combination of stimulus and response may have a unique C_{50}. When C_{50} is defined as the drug concentration that produces a given response in 50% of patients, a 50% probability of response is also likely in a given patient. Defining C_{50} as the concentration that produces a given drug effect in 50% of individuals implicitly assumes that the effect can be achieved in all individuals. Some drugs exhibit a ceiling effect. For example, a ceiling effect may exist on the ability of opioids to suppress response to noxious stimulation. When a ceiling in drug effect exists, some patients may not exhibit the drug effect even at infinitely large doses. In this case, C_{50} is not the concentration that causes the drug effect in 50% of patients but is the concentration associated with the drug effect in one half of whatever fraction of patients is able to respond.

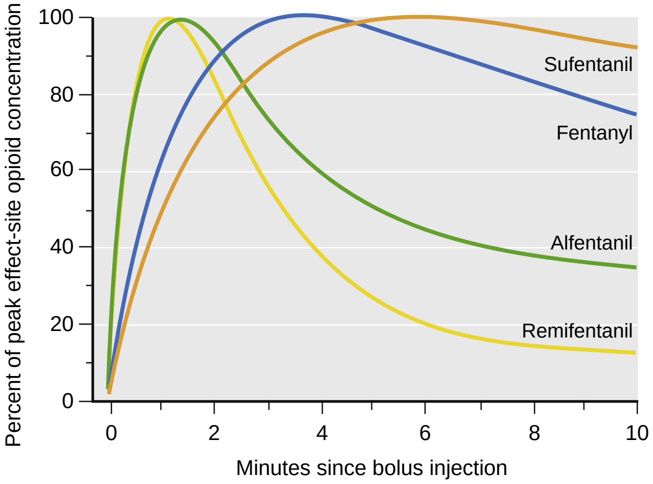

Fig. 26.8 Simulated onset and time to peak effect of commonly used opioids based on their k_{e0} and pharmacokinetic parameters. k_{e0}, Rate constant for the transfer of drug from the site of drug effect to the environment.

Several studies have been performed to establish appropriate concentrations of intravenous anesthetics and opioids for various clinical endpoints and the effect of drug interactions (Table 26.2).[49-56]

Another interpretation of C_{50} is the concentration that produces 50% of the maximum possible physiologic response. For example, the C_{50} for an EEG response is the drug concentration that provides 50% depression of the maximal EEG effect. The C_{50} for EEG response has been measured for the opioids alfentanil,[57] fentanyl,[57] sufentanil,[58] and remifentanil.[59-61] It has also been determined for thiopental,[51,62,63] etomidate,[56] propofol,[24] and benzodiazepines (see Table 26.2).[57,64] Other measures such as pupillary dilation in response to a noxious stimulus[65] and pressure algometry[22] were used to measure opioid potency and revealed slightly different values for C_{50}, which indicates that observation of drug potency also depends on the applied measure of drug effect.

As mentioned, C_{50} can be used to compare potency among drugs. For example, Glass and colleagues[66] determined the potency of remifentanil compared with alfentanil using ventilatory depression as the measure of opioid effect. In their study, the C_{50} for depression of minute ventilation was 1.17 ng/mL and 49.4 ng/mL for remifentanil and alfentanil, respectively. Using this difference in C_{50},

TABLE 26.2 Steady-State Concentrations for Predefined Effects

Drug	C_{50} for EEG Depression[*]	C_{50} for Incision or Painful Stimulus[†]	C_{50} for Loss of Consciousness[‡]	C_{50} for Spontaneous Ventilation[§]	C_{50} for Isoflurane MAC Reduction	MEAC
Alfentanil (ng/mL)	500-600	200-300	—	170-230	50	10-30
Fentanyl (ng/mL)	6-10	4-6	—	2-3	1.7	0.5-1
Sufentanil (ng/mL)	0.5-0.75	(0.3-0.4)	—	(0.15-0.2)	0.15	0.025-0.05
Remifentanil (ng/mL)	10-15	4-6	—	2-3	1.2	0.5-1
Propofol (μg/mL)	3-4	4-8	2-3	1.33	—	—
Thiopental (μg/mL)	15-20	35-40	8-16	—	—	—
Etomidate (μg/mL)	0.53	—	0.55	—	—	—
Midazolam (ng/mL)	250-350	—	125-250	—	—	—

[*] C_{50} for depression of the EEG is the steady-state serum concentration that causes a 50% slowing of the maximal EEG, except for midazolam, in which the C_{50} is associated with 50% activation of the EEG.

[†] C_{50} for skin incision is the steady-state plasma concentration that prevents a somatic or autonomic response in 50% of patients.

[‡] C_{50} for loss of consciousness is the steady-state plasma concentration for absence of a response to a verbal command in 50% of patients.

[§] C_{50} for spontaneous ventilation is the steady-state plasma concentration associated with adequate spontaneous ventilation in 50% of patients.

Values in parentheses are estimated by scaling to the alfentanil C_{50} (see text for details).

EEG, Electroencephalography; *MAC,* minimum alveolar concentration; *MEAC,* minimum effective plasma concentration providing postoperative analgesia.

they concluded that remifentanil is approximately 40 times more potent than alfentanil.

To be entirely independent of dosing history, C_{50} must be determined at steady state, which is rarely possible because most anesthetic drugs do not reach steady state during a continuous infusion until many hours have passed. However, if the drug exhibits rapid equilibration between plasma and the effect site and the investigator waits long enough after starting the infusion, then this choice can be reasonably satisfactory. For example, Ausems and colleagues[67,68] used a continuous infusion of alfentanil in their experiments, which quickly equilibrated. They also recorded their measurements after the effect-site concentration had equilibrated with plasma.

A second alternative to performing a true steady-state experiment is to use mathematic modeling to calculate the effect-site concentrations of drug at the time of measurement, as proposed by Hull and colleagues[16] and Sheiner and colleagues.[17] The relationship between effect-site and plasma concentrations is graphically represented in Fig. 26.5 and mathematically in Eq. 26.6. Calculating effect-site concentrations is the same as attempting to determine the steady-state plasma concentrations that produce the observed drug effect. When the C_{50} reflects effect-site concentrations, it is represented as Ce_{50} to distinguish it from values of C_{50} that are based on plasma concentrations, which are then termed Cp_{50}. However, the distinction is artificial. In both cases, C_{50} is intended to represent the steady-state plasma drug concentration associated with a given drug effect.

A third alternative to performing a steady-state experiment is to establish a pseudo–steady state with the use of computer-controlled drug delivery. By this term we mean that a steady state is assumed to exist, because a varying rate drug infusion is being administered with the intent of achieving stable plasma concentrations. This method has become the state of the art for determining the C_{50} for anesthetic drugs, and many of the C_{50} values referenced earlier were determined at pseudo–steady state with the use of computer-controlled drug delivery. Commonly, two or more measurements of the plasma concentration during pseudo–steady state conditions are performed to verify whether this is indeed the case.[40-42] Typically, maintaining a constant plasma steady-state concentration for four to five plasma effect-site equilibration half-lives (e.g., 10-15 minutes for fentanyl) is required. Such a long delay is not necessarily needed when computer-controlled drug delivery is used.

Effect-compartment TCIs can be used to target the concentration at the effect site rather than the plasma concentration and thereby rapidly establishing plasma–effect site equilibration.[29,47] For example, Kodaka and associates reported predicted values of propofol effect-site concentration C_{50} between 3.1 μg/mL and 4.3 μg/mL for insertion of various laryngeal airway masks, depending on the type of laryngeal mask.[69] Cortinez and associates used TCI to determine the C_{50} of remifentanil and fentanyl for accurate pain relief during extracorporeal shock wave lithotripsy in relation with possible side effects and found that remifentanil and fentanyl C_{50} were 2.8 ng/mL and 2.9 ng/mL, respectively.[70] At C_{50}, the probability of having a respiratory rate less than 10 breaths per minute was 4% for remifentanil and 56% for fentanyl.

Likewise, TCI has been used to estimate the following C_{50} values for dexmedetomidine: the C_{50} for half-maximal effect on the BIS (BIS ~48) was 2.6 ng/mL, for half-maximal effect on the Modified Observer's Assessment of Alertness/Sedation (MOAA/S) scale was 0.438 ng/mL, for half-maximal hypotensive effect was 0.36 ng/mL, and the C_{50} for half-maximal hypertensive effects was 1.6 ng/mL.[71,72]

Thus there are several ways to establish C_{50} in terms of steady-state concentrations. C_{50} can be estimated through mathematic effect-site modeling or can be experimentally measured with the use of computer-controlled drug delivery to establish a pseudo–steady state quickly. Either way, when performing studies to define the concentration-effect relationship, equilibrium must exist or be modeled between the biophase (the site of effect) and plasma or blood (where the concentration is actually measured).

When C_{50} is defined in terms of the concentration associated with a response in one half of a population, that same C_{50} is the concentration associated with a 50% probability of response in a typical individual. However, individual patients are not typical individuals but rather will have their own value for C_{50}. Expressed in clinical terms, different patients have different anesthetic requirements for the same stimulus. For example, the minimal effective analgesic concentration of fentanyl is 0.6 ng/mL, but it varies among patients from 0.2 to 2.0 ng/mL.[73] The minimal effective analgesic concentrations of alfentanil[74] and sufentanil[75] similarly vary among patients by a factor of 5 to 10. This range encompasses both variability in the intensity of the stimulus and variability of the individual patient.

One factor known to be responsible for this interindividual pharmacodynamic variability is the patient age. Thus with the pharmacodynamic for propofol developed by Eleveld and colleagues, and based on pharmacokinetic-pharmacodynamic data from a large number of patients and volunteers, the estimated effect-site propofol concentrations required for a BIS of 47 for patients whose ages are 20, 40, and 70 years, are 3.5, 3.1, and 2.6 ug/mL, respectively.[76]

Although age has a strong effect on the C_{50}, it does not explain all the variability. This wide range reflects the clinical reality that must be accounted for when dosing regimens are designed. Because of this variability, intravenous anesthetics should be titrated to each patient's unique anesthetic requirement for the given stimulus.

Pharmacodynamic Drug Interactions

Drug interactions cause the potency of one drug (e.g., as measured by the C_{50}) to shift in response to the administration of a second drug. This drug interaction can be additive, supra-additive (synergistic), or infra-additive (antagonistic). As observed in the isobologram (Fig. 26.9), for additive drugs with equal potency, the cumulative effect resulting from doses a and b for substances A and B, respectively, equals the effect obtained with the injection of either drug A or B solely in a dose a + b. If the drugs interact synergistically, then the combination of A and B will generate a more pronounced effect than additive. For antagonistic drug interaction, the combination of A and B will result in a less pronounced effect than additive. In general, additive drug interactions occur when combining drugs acting by the same mechanism and synergistic or antagonistic interaction when combining drugs acting by a different mechanism.[77] Hendrickx and coworkers (Fig. 26.10) reviewed the available literature and summarized the available data on drug interactions in humans and animals for hypnosis and immobility.[77]

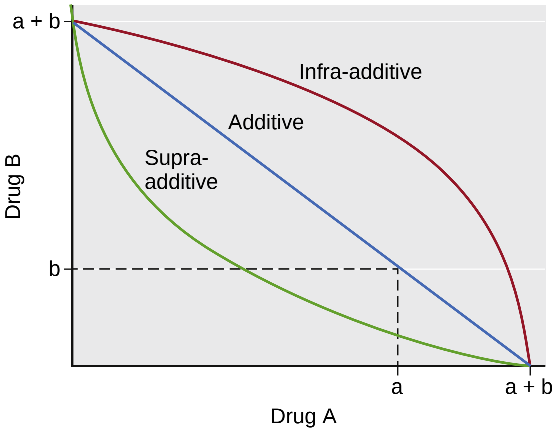

Fig. 26.9 Pharmacodynamic drug interactions.

Investigating only one isobole of the interaction spectrum (e.g., the 50% probability level of a specific drug response) provides a rudimentary insight into the interaction characteristics but reveals only limited information about other levels of drug effect (e.g., at the clinically more important level of 95% probability of drug response). As drug interactions may vary among drug effect levels (e.g., additive at the 50% level but synergistic at the 95% level), the ultimate aim is to characterize the response surface describing all levels of effect. Pharmacodynamic response surface models generate figures that are three- (or even higher) dimensional structures that have been developed to describe the relationship quantitatively between two or more drug concentrations and their combined clinical effect (Fig. 26.11). Response surface models are powerful representations of drug interactions as they combine information about the full range of isoboles resulting from the concentration response curves of all combinations of the drugs involved.[78,79] Using the mathematically defined response surface, the corresponding drug effect for any two or more drug concentrations of the interacting drugs can be predicted.[80,81] Various methodological approaches to response surface models are found in the literature.[82]

Intravenous opioids are frequently combined with volatile anesthetics during anesthesia. The reduction of the MAC for a given volatile by a given opioid dose can be applied to investigate the potency and efficacy of opioids.[83-85] These MAC reduction studies reveal a general pattern, irrespective of which opioid or volatile anesthetic has been used. Low concentrations of an opioid result in a substantial reduction of MAC (Fig. 26.12). With increasing concentrations of the opioid, MAC continues to decrease until a plateau is reached and, consequently, a further increase of the opioid dose is futile.[86]

The previously mentioned MAC reduction studies show the effect of a single opioid dose on a single point of a dose-response curve but, nonetheless, form the basis for more detailed surface interaction studies.[87] To characterize the interaction between sevoflurane and remifentanil in blunting responses to verbal (OAA/S scale) and painful stimuli (pressure algometry, electrical tetanic stimulus, and thermal stimulation), Manyam and coworkers constructed a response surface for each pharmacodynamic response using a Logit model approach and found synergy between sevoflurane and remifentanil for all responses. More specifically, a remifentanil effect-site concentration of 1.25 ng/mL was able to more than halve the sevoflurane requirements for preventing movement to pain.[88] Because this study suffered from nonsteady-state conditions at the moment of measurements, the authors improved their data using calculated effect-site sevoflurane concentrations and a Greco model instead of a Logit approach.[89] Accounting for the time lag between sevoflurane effect-site concentration and end-tidal concentration improved the predictions of responsiveness during anesthesia but had no effect on the accuracy of prediction of a response to a noxious stimulus in recovery. They concluded that models may be useful in predicting events of clinical interest, but large-scale evaluations with numerous patients are needed to better characterize model performance. Heyse and colleagues (Fig. 26.13) found that the pharmacodynamic interaction between sevoflurane and remifentanil for tolerance to shaking and shouting (TOSS), tetanic stimulation (TTET), laryngeal mask airway insertion (TLMA), and laryngoscopy (TLAR) using the Fixed $C50_O$ Hierarchical model was strongly synergistic for both the hypnotic and the analgesic components of anesthesia and showed the importance of exploring various surface model approaches when studying drug interactions.[82,90]

For total intravenous anesthesia, interactions associated with various drug combinations and concentrations have been described. The concept of *balanced* anesthesia is based on the assumption that drug combinations will be synergistic in anesthetic effect (however defined) but not in toxicity. Such synergism has been demonstrated for a variety of drug combinations but not for others (see Fig. 26.10).[77,91] Zanderigo and colleagues[92] developed the *well-being model*, a new interaction model to describe both positive and negative effects of drug combinations (Fig. 26.14).

Fig. 26.10 Interaction grid summarizing the available data on drug interactions in humans and animals for hypnosis and immobility. Drugs are organized by pharmacologic class: gamma-aminobutyric acid *(GABA)*–acting drugs (propofol, thiopental, methohexital, and etomidate); GABA agents acting at the benzodiazepine *($GABA_{BDZ}$)*-binding site (midazolam, diazepam); *N*-methyl-D-aspartate *(NMDA)*-receptor antagonist (ketamine); adrenergic agonists *(α_2)* (dexmedetomidine, clonidine); opioid-acting drugs at opioid receptor (morphine, alfentanil, fentanyl, sufentanil, and remifentanil); dopamine at dopamine antagonists (droperidol, metoclopramide); sodium (Na^+) channel blockers (lidocaine, bupivacaine); and anesthetic gases. The right upper half of the grid *(above the thick diagonal)* summarizes the interactions for the endpoint of immobility; the left lower half *(below the thick diagonal)* summarizes the interactions for the endpoint of hypnosis. Synergy is coded as *green*, additivity as *yellow*, and infra-additivity as *dark orange*. The number refers to the number of studies attesting to a particular interaction; if one study documents two interactions (e.g., isoflurane with both fentanyl and alfentanil), then they are counted separately. Animal data carry the suffix *a* after the number of studies, human data have no suffix. *Reanalysis: propofol-ketamine interaction in humans is infra-additive for immobility. **Reanalysis: thiopental-midazolam interaction in humans is additive for hypnosis. †Because the MAC of Xe in swine is uncertain, data in swine are not included. ¶Reanalysis: ketamine-midazolam interaction in humans is infra-additive for hypnosis and additive for immobility. §Infra-additivity between desflurane and nitrous oxide *(N_2O)* has been suggested in a small subgroup of 18- to 30-year-old patients. (From Hendrickx JF, Eger EI 2nd, Sonner JM, et al. Is synergy the rule? A review of anesthetic interactions producing hypnosis and immobility. Anesth *Analg.* 2008;107:494–506. Used with permission.)

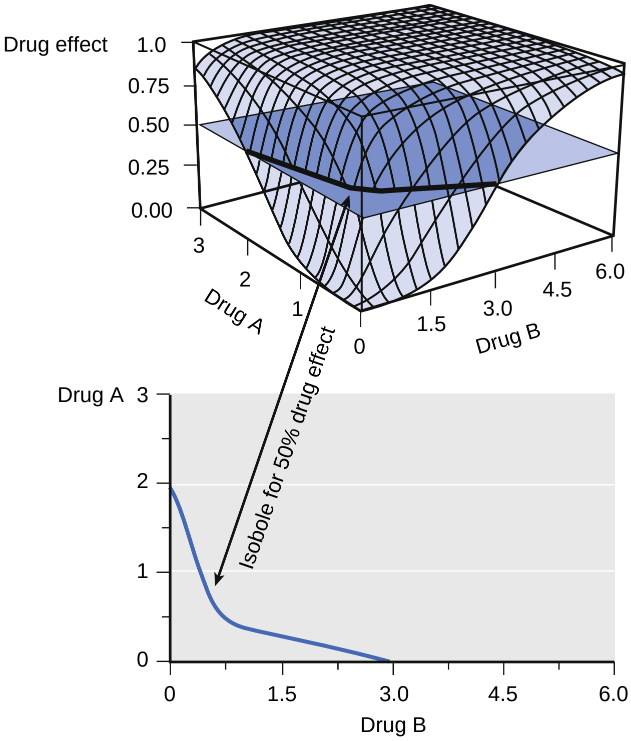

Fig. 26.11 Relationship between a response surface and a standard isobologram. Conventional isobolographic analysis, whether for doses or concentrations, describes only the concentration of both drugs that yields a 50% drug effect and thus fails to capture the entire response surface. (From Minto CF, Schnider TW, Short TG, et al. Response surface model for anesthetic drug interactions. *Anesthesiology.* 2000;92:1603–1616. Used with permission.)

More profound synergy for specific endpoints related to analgesia and hypnosis has also been demonstrated for the interaction between propofol and opioids. Thus when anesthetic regimens are designed that rely on synergy to produce the anesthetic state, distinguishing the desired endpoint—loss of consciousness or ablation of response to noxious stimulation—is important. Different combinations of drugs may be used to achieve any endpoint. Vuyk and colleagues characterized the interaction between propofol and alfentanil for several endpoints: loss of response to endotracheal intubation, loss of response to incision and retraction of the peritoneum, and emergence from anesthesia (Fig. 26.15).[93] The most profound stimulation was tracheal intubation, and when no opioid was used, the abolition of responses to that stimulus required a propofol concentration equal to or more than 12 μg/mL. More details for optimal drug combinations based on the findings from Vuyk and coworkers[93] are provided in Table 26.3.

Minto and colleagues published *response surfaces* for combinations of midazolam-alfentanil, propofol-alfentanil, and midazolam-propofol associated with the loss of response to verbal command (Fig. 26.16).[78] They also extended response surface methodology to describe the simultaneous interaction of three drugs. Rendering the full interaction surface for three drugs would require drawing the graph in four dimensions. If the graph is limited to the interaction at 50% drug effect, then it can be rendered in three dimensions (Fig. 26.17).

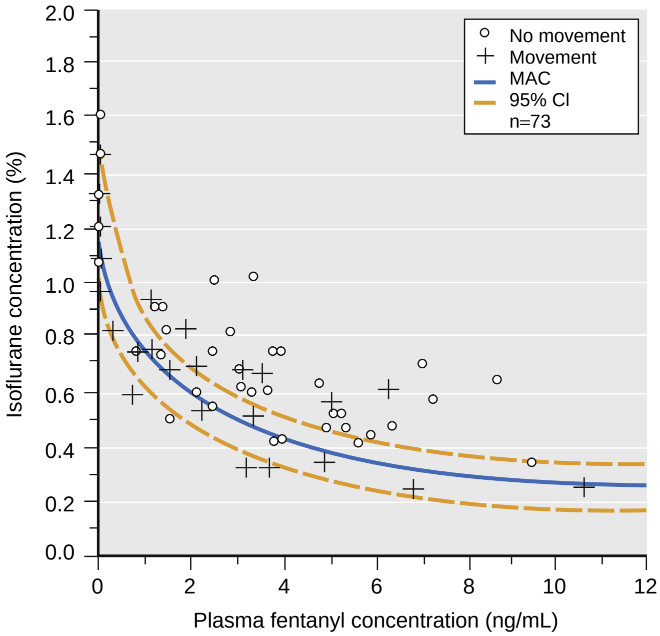

Fig. 26.12 Interaction of isoflurane and fentanyl in preventing a somatic response at skin incision (i.e., minimum alveolar concentration *[MAC]* reduction of isoflurane). The *blue line* represents the concentrations of isoflurane and fentanyl when administered together that are required to prevent purposeful movement in 50% of patients at skin incision. The *dotted gold lines* represent the 95% confidence interval *(CI)* of the MAC at each combination of fentanyl and isoflurane. (From McEwan AI, Smith C, Dyar O, et al. Isoflurane MAC reduction by fentanyl. *Anesthesiology.* 1993;78:864–869. Used with permission.)

In addition to studies of quantal responses, various studies investigated the interaction between hypnotics and opioids as measured with continuous measures. The effect of combined drug administration on spontaneous and evoked EEG–derived indices was found to be important and existing but often in studies that did not provide sufficient data for full-response surface model development.[24,94,95] Fortunately, more accurately designed studies[81] using surface modeling techniques revealed the interaction between hypnotics and opioids. Bouillon and colleagues found synergy between propofol and remifentanil regarding hypnosis as measured by the BIS and EEG approximate entropy. They also found that both indices were more sensitive to propofol than remifentanil.[96] Others found conflicting results for the effect of opioids on the BIS.[97] More recently, Gambus and colleagues modeled the effect of propofol and remifentanil combinations for sedation-analgesia in endoscopic procedures using an adaptive neurofuzzy inference system.[98] Both spontaneous and evoked EEG–derived indices (e.g., BIS or autoregressive auditory-evoked potential index [AAI/2] and index of consciousness [IoC]) were used. They found, based on these models, that the propofol and remifentanil effect-site concentration pairs provide a Ramsay Sedation Score of 4 ranging from (1.8 μg/mL, 1.5 ng/mL) to (2.7 μg/mL, 0 ng/mL), associated with a BIS of 71 to 75, AAI/2 values of 25 to 30, and IoC of 72 to 76, respectively. The presence of noxious stimulation increases the requirements of propofol and remifentanil to achieve the same degree of sedative effects.[98]

Other effects of drug combinations were also studied. Bouillon and associates and Nieuwenhuijs and associates

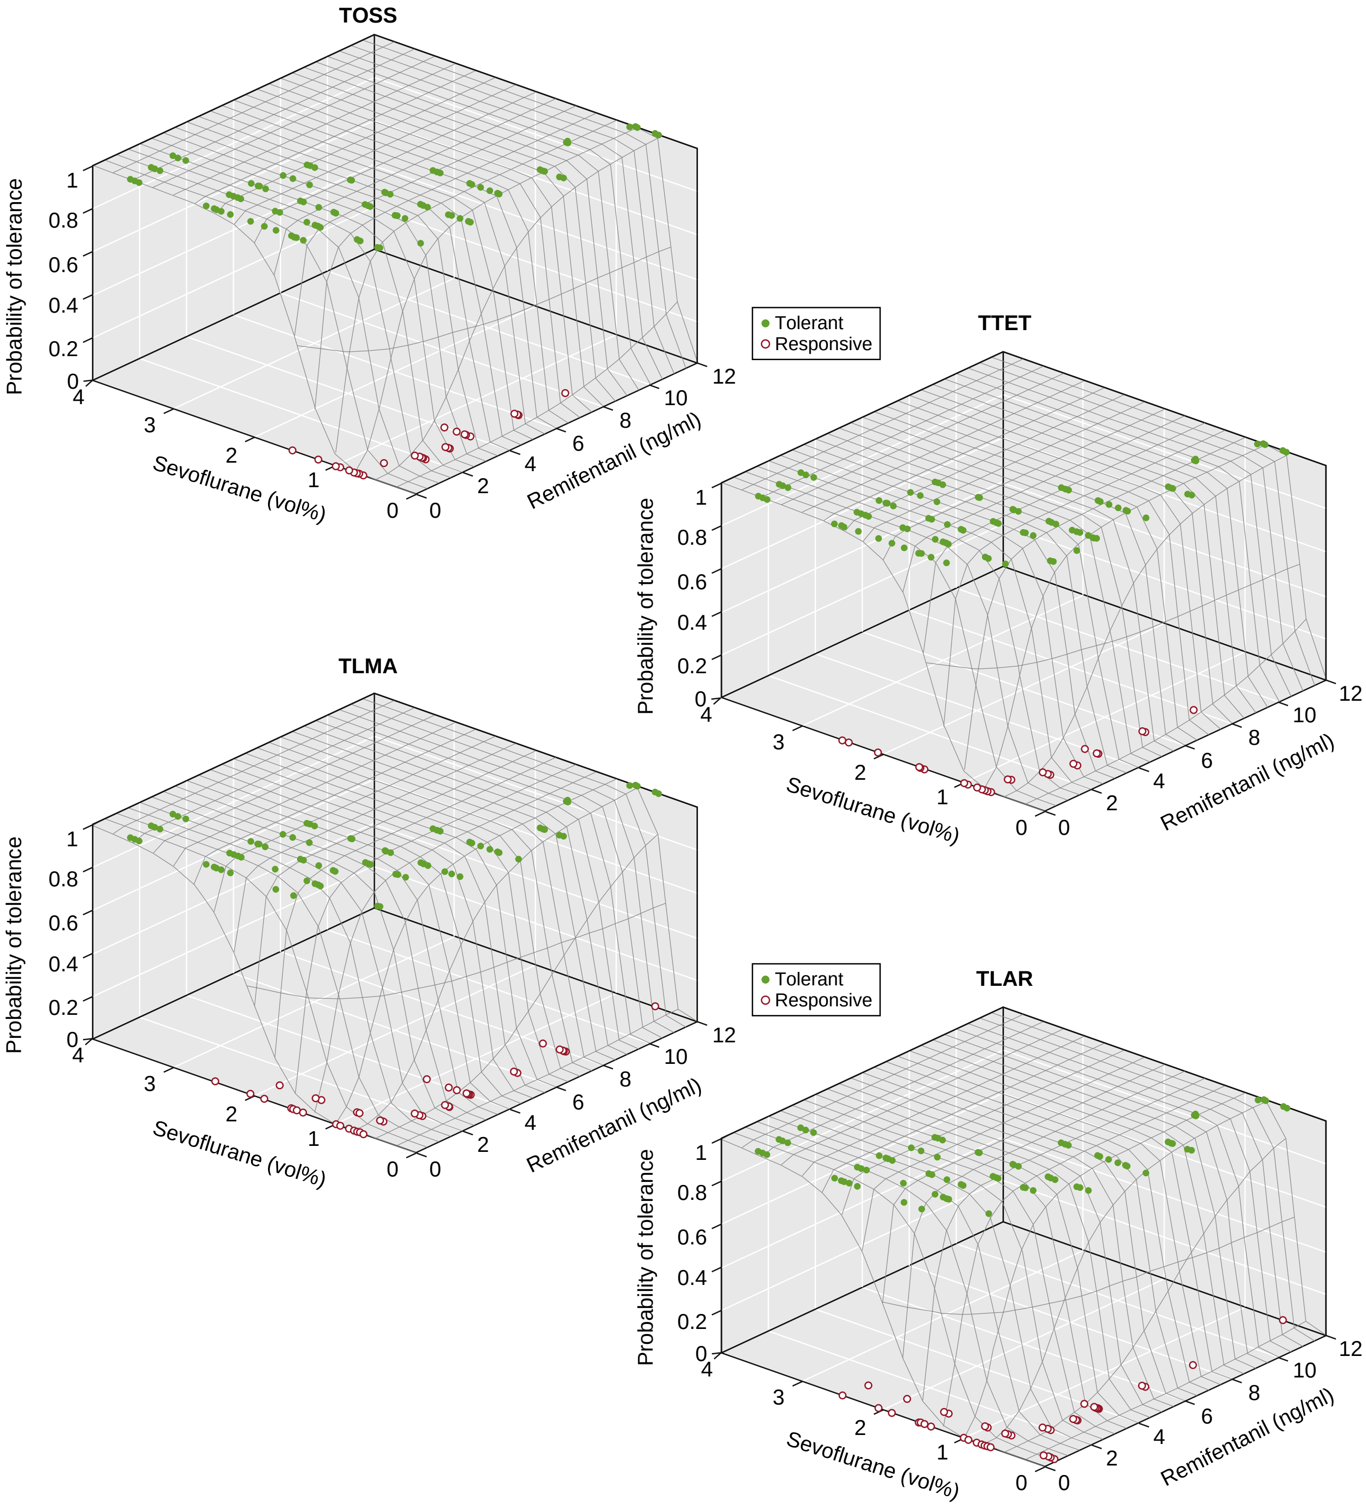

Fig. 26.13 Response surface for probability of tolerance to shaking and shouting *(TOSS)*, tetanic stimulation *(TTET)*, laryngeal mask airway insertion *(TLMA)*, and laryngoscopy *(TLAR)* for the Fixed C50(O) Hierarchical model. The solid lines at probability 0.5 represent the 50% isoboles. (From Heyse B, Proost JH, Schumacher PM, et al. Sevoflurane remifentanil interaction. comparison of different response surface models. *Anesthesiology*. 2012;116:311–323. Used with permission.)

investigated the effects of hypnotic-opioid combinations on cardiorespiratory control.[97,99] These data show dose-dependent effects on respiration at relatively low concentrations of propofol and remifentanil. When combined, their effect on respiration is strikingly synergistic, resulting in severe respiratory depression.

Surface models were also used to optimize drug administration in challenging situations such as short-duration

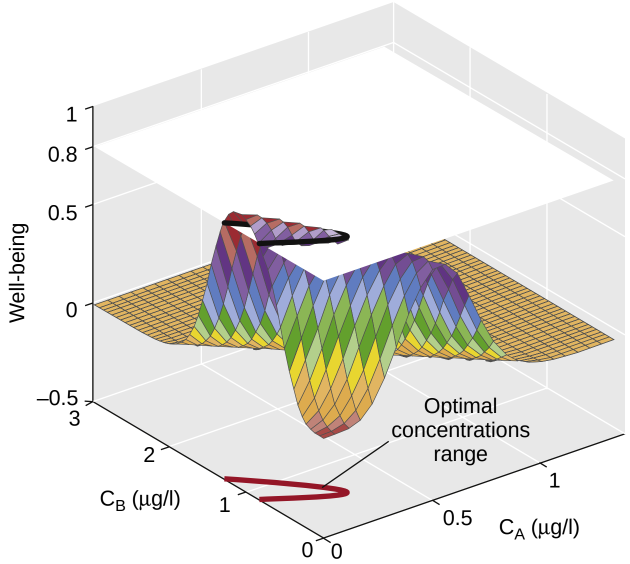

Fig. 26.14 Definition of the optimal concentrations range for the combined administration of drugs A and B, in the case of zero interactions. The optimal concentrations range results from the intersection between the well-being surface and the plane representing a well-being value of 0.8. (From Zanderigo E, Sartori V, Sveticic G, et al. The well-being model. A new drug interaction model for positive and negative effects. *Anesthesiology.* 2006;104:742–753. Used with permission.)

Response to intubation *(blue line)*, maintenance of anesthesia *(gold line)*, and concentrations associated with emergence from anesthesia *(green line)*. The curve shows the concentrations associated with a 50% probability of the respective endpoint. (Modified from Vuyk J, Lim T, Engbers FH, et al. The pharmacodynamic interaction of propofol and alfentanil during lower abdominal surgery in women. *Anesthesiology.* 1995;83:8–22.)

procedures in spontaneous breathing patients. LaPierre and coworkers[100] explored remifentanil-propofol combinations that led to a loss of response to esophageal instrumentation, a loss of responsiveness, and/or an onset of ventilatory depression requiring intervention. They found that the combinations that allowed esophageal instrumentation and avoided intolerable ventilatory depression and/or loss of responsiveness primarily clustered around remifentanil-propofol effect-site concentrations ranging from 0.8 to 1.6 ng/mL and 1.5 to 2.7 µg/mL, respectively. However, blocking the response to esophageal instrumentation and avoiding both intolerable ventilatory depression and/or a loss of responsiveness is difficult. It may be necessary to accept some discomfort and blunt, rather than block, the response to esophageal instrumentation to consistently avoid intolerable ventilatory depression and/or loss of responsiveness.

In a previously mentioned study, using response surface modeling, Bouillon and colleagues also determined the interactions between propofol and remifentanil on the probability to tolerate laryngoscopy (PTOL).[96] Luginbuhl, working with a group that included Bouillon, normalized and calibrated PTOL, to produce an index called the noxious stimulus response index (NSRI).[101] The NSRI is a dimensionless integer number between 0 and 100, where 50 corresponds to a PTOL of 50% and 20 to a PTOL of 90%.

The interactions between hypnotics such as propofol and sevoflurane should also be understood, because these drugs are frequently used sequentially. Schumacher and colleagues[102] used response surface methodology to examine the influence of this interaction on the probability of TOSS and three noxious stimuli (TTET, TLMA, and TLAR). They found that for both EEG suppression and tolerance to stimulation, the interaction of propofol and sevoflurane were additive. Others found similar results on the C_{50} level.[103] Hammer and colleagues[104] determined the pharmacodynamic interaction of propofol and dexmedetomidine during pediatric esophagogastroduodenoscopy and concluded that the concentration of propofol at which 50% of patients are adequately anesthetized (EC_{50}) in children was unaffected by a concomitant intravenous infusion of dexmedetomidine 1 µg/kg body weight given over 10 minutes.

Hannivoort and colleagues took this work a step further by using response surface modeling to develop a model that predicts the effect of combinations of sevoflurane, propofol, and remifentanil in terms of PTOL and the NSRI.[105]

Although models of the pharmacokinetics and pharmacodynamics of drug, and models of drug interactions, are essentially just that—models that attempt to provide qualitative and quantitative representations of reality—they are based on many assumptions, and inherently involve many sources of error.[106] Nonetheless, the models provide information that is useful to clinicians to help guide rational practice. Information on drug interactions, including the NSRI, has been incorporated in commercially available anesthetic display monitors and are described by van den Berg and associates in a concise summary of current knowledge, and the ways that it has and can be incorporated into clinical practice.[107]

Designing Dosing Regimens

BOLUS DOSE CALCULATIONS

The definition of concentration is drug mass per unit of volume. The definition of concentration can be rearranged to find the amount of drug required to produce any desired concentration for a known volume (Eq. 26.10):

$$Amount = C_T \bullet Volume \qquad (26.10)$$

TABLE 26.3 Propofol/Opioid Combinations Associated with the Fastest Recovery from Anesthesia

Infusion Duration (min)		Propofol/Alfentanil (μg/mL; ng/mL)	Propofol/Sufentanil (μg/mL; ng/mL)	Propofol/Remifentanil (μg/mL; ng/mL)
15	$C_{optimal}$	3.25/99.3	3.57/0.17	2.57/4.70
	$C_{awakening}$	1.69/65.0	1.70/0.10	1.83/1.93
	Time to awakening (min)	8.2	9.4	5.1
60	$C_{optimal}$	3.38/89.7	3.34/0.14	2.51/4.78
	$C_{awakening}$	1.70/64.9	1.70/0.10	1.83/1.93
	Time to awakening (min)	12.2	11.9	6.1
300	$C_{optimal}$	3.40/88.9	3.37/0.14	2.51/4.78
	$C_{awakening}$	1.70/64.9	1.70/0.10	1.86/1.88
	Time to awakening (min)	16.0	15.6	6.7

$C_{optimal}$ represents combinations associated with a 50% probability of a response to surgical stimuli; $C_{awakening}$ concentrations represent the estimated concentrations at which consciousness will be regained; and Time to awakening represents the estimated time from termination of the infusion to return of consciousness in 50% of patients.

From Vuyk J, Mertens MJ, Olofsen E, et al. Propofol anesthesia and rational opioid selection. Determination of optimal EC_{50}-EC_{95} propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. *Anesthesiology*. 1997;87:1549–1562; and modified from Absalom A, Struys MMRF. *An Overview of TCI and TIVA*. ed 2. Gent, Belgium: Academia Press; 2007. Used with permission.

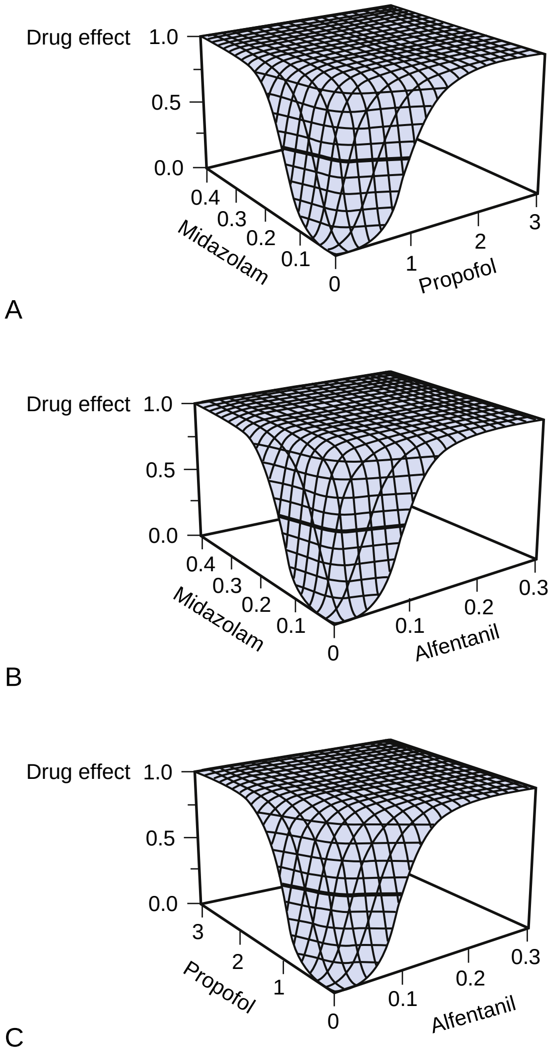

Fig. 26.16 Response surface for each of the paired interactions between propofol and midazolam (A), alfentanil and midazolam (B), and alfentanil and propofol (C) on the probability of opening eyes to a verbal command. The isoboles for a 10%, 20%, 30%, 40%, 50%, 60%, 70%, 80%, and 90% response are shown. (From Minto CF, Schnider TW, Short TG, et al. Response surface model for anesthetic drug interactions. *Anesthesiology*. 2000;92:1603–1616.)

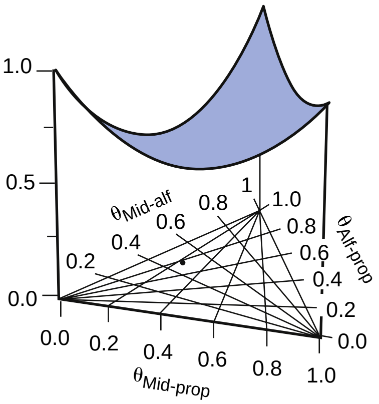

Fig. 26.17 Interaction at 50% drug effect (C_{50}) among propofol, midazolam, and alfentanil. Downward deflection of the surface represents synergy, in units of fractional reduction in C_{50}. The three edges represent relative amounts of propofol to midazolam *($\theta_{Mid\text{-}prop}$)*, alfentanil to midazolam *($\theta_{Mid\text{-}alf}$)*, and alfentanil to propofol *($\theta_{Alf\text{-}prop}$)*. The surface between the edges represents the relative synergy of all three drugs taken together. (From Minto CF, Schnider TW, Short TG, et al. Response surface model for anesthetic drug interactions. *Anesthesiology*. 2000;92:1603–1616.)

where C_T is the desired or *target* concentration. This formula is often used to calculate the initial (loading) bolus dose required to achieve a given concentration. The problem with applying this concept to anesthetic drugs is that there are several volumes of distribution: V_1 (central compartment), V_2 and V_3 (the peripheral compartments), and Vd_{ss} (the sum of the individual volumes). V_1 is usually significantly smaller than Vd_{ss}, and thus saying that the loading dose should be something between $C_T \times V_1$ and $C_T \times Vd_{ss}$ is tempting.

Consideration should be given to the dose of fentanyl required to attenuate the hemodynamic response to endotracheal intubation when combined with thiopental. The C_{50} for fentanyl, combined with thiopental for intubation, is approximately 3 ng/mL. The V_1 and Vd_{ss} for fentanyl are 13 L and 360 L, respectively. The aforementioned equations can thus be interpreted as suggesting that an appropriate dose of fentanyl to attenuate the hemodynamic response is between 39 μg (3 ng/mL × 13 L) and 1080 μg (3 ng/mL

× 360 L). A fentanyl bolus of 39 µg achieves the desired concentration in plasma for an initial instant, but plasma levels almost instantly decrease below the desired target. Levels at the effect site will never be close to the desired target concentration of 3 ng/mL. A fentanyl bolus of 1080 µg, not surprisingly, produces a significant overshoot in plasma levels that persists for hours (Fig. 26.18). Additionally, using equations to calculate the fentanyl dose if the resulting recommendation is to "use a fentanyl dose between 39 and 1080 µg" is absurd.

The usual dosing guidelines for a bolus dose, presented earlier, are designed to produce a specific plasma concentration. Because plasma is not the site of drug effect, calculating the initial bolus on the basis of a desired plasma concentration is irrational. By knowing the k_{e0} of an intravenous anesthetic, a dosing regimen can be designed that yields the desired concentration at the site of drug effect. To avoid an overdose for the patient, a bolus should be selected that produces the desired peak concentration at the effect site.

The decline in plasma concentration between the initial concentration after the bolus (amount/V_1) and the concentration at the time of peak effect can be thought of as dilution of the bolus into a larger anatomic volume than the volume of the central compartment. This introduces the concept of Vd_{pe}, the apparent volume of distribution at the time of peak effect,[28,94] or pseudoequilibration between plasma and the site of drug effect.[95] The size of this volume can be readily calculated from the observation that the plasma and effect-site concentrations are the same at the time of peak effect (Eq. 26.11):

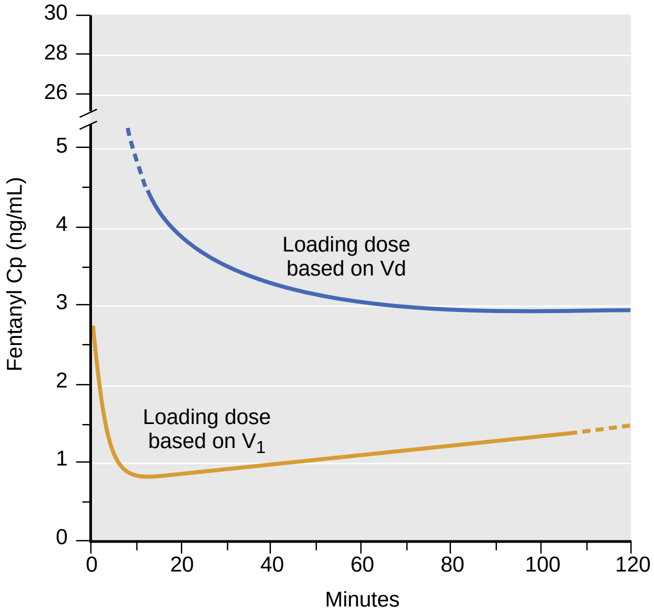

Fig. 26.18 Pharmacokinetic simulation demonstrating the limitations of infusion regimens based on simple pharmacokinetic parameters with fentanyl used as an example. These infusion schemes were designed to achieve a fentanyl plasma concentration *(Cp)* of 3 ng/mL. The *upper blue curve* shows that a regimen using a loading dose based on the volume of distribution followed by a constant infusion based on clearance results in a transient period of very high plasma concentrations. If the same maintenance infusion is given but the loading dose is based on the volume of the central compartment, then the distribution of drug to the peripheral compartments causes the plasma concentration to fall below the desired level until the compartments reach steady-state concentrations as shown in the *lower gold curve*.

$$Vd_{pe} = \frac{Bolus\ amount}{C_{pe}} \qquad (26.11)$$

where C_{pe} is the plasma concentration at the time of peak effect.

If the clinical goal is to select the dose required to achieve a certain drug effect without producing an overdose, then Eq. 26.11 can be rearranged by substituting C_T, the target concentration (which is the same in plasma and the effect site at the moment of peak effect), for C_{pe} to calculate the size of the initial bolus (Eq. 26.12)

$$Loading\ dose = C_T \times Vd_{pe} \qquad (26.12)$$

The Vd_{pe} for fentanyl is 75 L. To achieve a peak fentanyl effect-site concentration of 3.0 ng/mL requires 225 µg, which produces a peak effect in 3.6 minutes. This dosing guideline is more reasonable compared with the previous recommendation of a dose between 39 and 1080 µg. Table 26.4 lists V_1 and Vd_{pe} for fentanyl, alfentanil, sufentanil, remifentanil, propofol, thiopental, and midazolam. Table 26.1 lists the time to peak effect and the $t_{1/2}\ k_{e0}$ of the commonly used intravenous anesthetics.

MAINTENANCE INFUSION RATES

By definition, the rate at which active drug exits the body is systemic clearance (Cl_S) times the plasma concentration. To maintain a given target concentration (C_T), drug must be delivered at the same rate that it is exiting the body. Thus (Eq. 26.13),

$$Maintenance\ infusion\ rate = C_T \times Cl_S \qquad (26.13)$$

For drugs with multicompartment pharmacokinetics, which includes all of the intravenous drugs used in anesthetic practice, drug is distributed into the peripheral tissues, as well as cleared from the body. The rate of distribution into tissues changes over time as the tissues equilibrate with plasma. Eq. 26.13 is correct only after the peripheral tissues have fully equilibrated with plasma, which requires many hours. At all other times, this maintenance infusion rate underestimates the infusion rate necessary to maintain a target concentration.

Yet in some situations, this simple maintenance rate calculation may be acceptable. For example, if an infusion at this rate is used along with a bolus dose based on Vd_{pe} and the drug has a long delay between the bolus and peak effect, then most of the distribution of drug into tissues may have occurred by the time that the effect-site concentration reaches the target concentration. In this case, the maintenance infusion rate calculated as clearance times target concentration may be accurate because Vd_{pe} is sufficiently higher than V_1 to account for the distribution of drug into peripheral tissues. Unfortunately, most drugs used in anesthesia achieve sufficiently rapid equilibration between plasma and the effect site that Vd_{pe} does not adequately encompass the distribution process, thus making this approach unsuitable.

As such, approaches need to be used that are mathematically and clinically sound. Because the net flow of drug into peripheral tissues decreases over time, the infusion rate required to maintain any desired concentration must also decrease over time. If the initial bolus has been based on

Vd_{pe}, no infusion needs be administered until the effect-site concentration peaks. After the peak in effect-site concentration, the (nearly) correct equation to maintain the desired concentration is (Eq. 26.14)

$$\text{Maintenance infusion rate} = C_T \times V_1 \times \left(k_{10} + k_{12}e^{-k_{21}t} + k_{13}e^{-k_{31}t}\right) \qquad (26.14)$$

This equation indicates that a rapid infusion rate is initially required to maintain C_T. Over time, the infusion rate gradually decreases (see Fig. 26.14). At equilibrium (t = ∞), the infusion rate decreases to $C_T \times V_1 \times k_{10}$, which is the same as $C_T \times Cl_S$. Few clinicians would choose to solve such an equation during the administration of an anesthetic. Fortunately, simple techniques can be used in place of solving such a complex expression.

TABLE 26.4 Volume of Distribution at the Time of Peak Effect

Drug	V_1 (L)	Vd_{pe} (L)
Fentanyl	12.7	75
Alfentanil	2.19	5.9
Sufentanil	17.8	89
Remifentanil	5.0	17
Propofol	6.7	37
Thiopental	5.6	14.6
Midazolam	3.4	31

V_1, Volume of the central compartment; *Vd_{pe}*, apparent volume of distribution at the time of peak effect.

Fig. 26.19 is a nomogram in which Eq. 26.14 has been solved; the infusion rates at different times necessary to maintain any desired concentration of fentanyl, alfentanil, sufentanil, and propofol are shown. Because this nomogram is complex, the following review is provided:

The *y* axis represents the target concentration C_T. The *x* axis is the time since the beginning of the anesthetic (i.e., since the initial bolus). The suggested initial target concentrations (shown in gold) are based on the work of Vuyk and colleagues[93] with propofol and alfentanil (see Fig. 26.15) and are scaled to fentanyl and sufentanil according to their relative potencies.[108] The intersections of the target concentration line and the diagonal lines indicate the infusion rate appropriate at each point in time. For example, to maintain a sufentanil concentration of 0.16 ng/mL, the appropriate rates are approximately: 0.6 µg/kg/h at 5 minutes, 0.5 µg/kg/h at 10 minutes, 0.4 µg/kg/h at 20 minutes, and 0.3 µg/kg/h at 40 minutes. Of course, selecting target concentrations and different times of rate adjustment is possible, depending on the clinical circumstances and an assessment of how accurately the intravenous drug needs to be titrated.

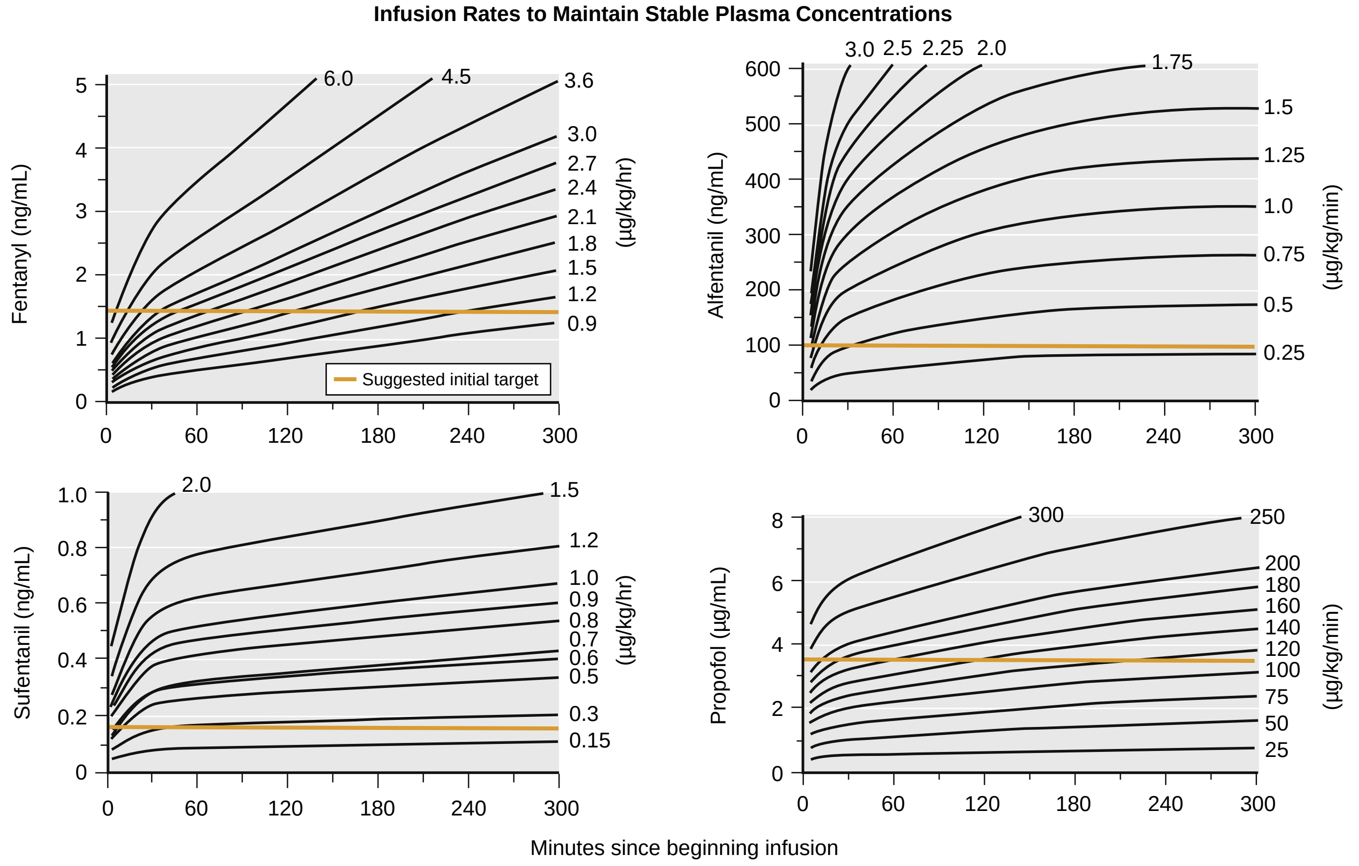

Fig. 26.19 Nomogram for calculating maintenance infusion rates to maintain a stable concentration of fentanyl, alfentanil, sufentanil, or propofol. The *y* axis is the desired concentration. The *x* axis is the time relative to the initial bolus. The *diagonal lines* show the infusion rates at different times required to maintain the desired concentration selected on the *y* axis.

RECOVERY FROM ANESTHESIA

Recovery from anesthesia is determined by the pharmacokinetic principles that govern the rate of decrease in drug from the effect compartment once drug administration is terminated, as well as by the pharmacodynamics of the drug. Although the terminal elimination half-life is often interpreted as a measure of how short- or long-lasting a drug is, the rate at which drug plasma concentration decreases is dependent on both elimination and redistribution of the drug from the central compartment. The contribution of redistribution and elimination toward the rate of decrease in drug concentration varies according to the duration for which the drug has been administered[108,109] and also the time since the infusion has stopped, because these processes have different rate constants.

In 1985, Schwilden[110] developed a mathematic model to relate the time course of offset of action of inhaled anesthetics to the duration of anesthetic drug delivery. Similarly, Fisher and Rosen[111] demonstrated how the accumulation of neuromuscular blocking agents in peripheral volumes of distribution results in slowed recovery with increasing duration of administration. They introduced two measures of the time course of recovery, the time for twitch tension to recover from 5% to 25% and the time for twitch tension to recover from 25% to 75%.

Since then, the time for the plasma concentration to decrease by 50% from an infusion that maintains a constant concentration (e.g., infusion given by (Eq. 26.14) has been termed the *context-sensitive half-time* (Fig. 26.20),[109] with the context being the duration of the infusion. The 50% decrease was chosen both for tradition (e.g., half-lives are the time for a 50% decrease with a one-compartment model) and because, very roughly, a 50% reduction in drug concentration appears to be necessary for recovery after the administration of most intravenous hypnotics at the termination of surgery. Depending on circumstances, decreases other than 50% may be clinically relevant. Additionally, sometimes it is the plasma concentration that is of interest, and sometimes it is the effect-site concentration that is of interest. A more general term is the context-sensitive *decrement time*,[112] in which the decrement in concentration is specifically noted, as is the compartment where the decrease is modeled (plasma or effect site). For example, the relationship between infusion duration and the time required for a 70% decrease in fentanyl effect-site concentration is the *context-sensitive 70% effect-site decrement time*.

Context-sensitive effect-site decrement times for varying percent decreases in alfentanil, fentanyl, sufentanil, and remifentanil concentration are illustrated in Fig. 26.21. To determine when an infusion should be terminated (to enable awakening of the patient at the end of surgery), the clinician needs to bear in mind the decrease in concentration necessary for recovery, the duration of the infusion (the context), and the context-sensitive, effect-site decrement time required for the necessary decrease.

Context-sensitive decrement times are fundamentally different from the elimination half-life. With monoexponential decay, each 50% decrease in concentration requires the same amount of time, and this time is independent of how the drug is given. This is not true for the context-sensitive half-time. First, as the name is intended to imply, the time needed for a 50% decrease is absolutely dependent on how long the drug was given, with infusion duration being the context to which the name refers. In addition, small changes in percent decrement can result in surprisingly large increases in the time required. The time required for a 60% decrease in drug concentration can be more than twice the time required for a 50% decrease in some situations (see Fig. 26.21).

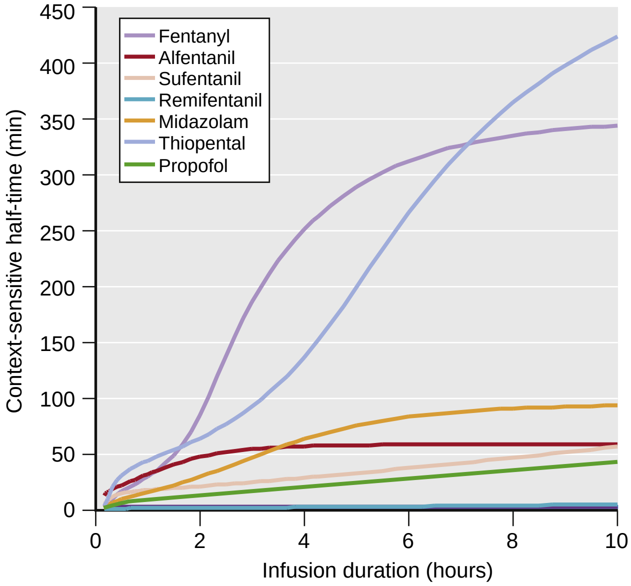

Fig. 26.20 Context-sensitive half-times as a function of infusion duration (context) derived from pharmacokinetic models of fentanyl, sufentanil, alfentanil, remifentanil, propofol, midazolam, and thiopental. (From Hughes MA, Glass PSA, Jacobs JR. Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. *Anesthesiology*. 1992;76:334–341.)

Context-sensitive decrement times are based on the assumption that plasma or the effect site is maintained at a constant concentration. Such is rarely the case clinically, but the maintenance of constant concentrations is a necessary assumption to provide a unique mathematic solution to the time required for a given percent decrement in plasma or effect-site concentration. Because plasma and effect-site concentrations are rarely kept constant, it is important that context-sensitive decrement times are used as *general* guidelines for interpreting the pharmacokinetics of intravenous drugs and not as *absolute* predictions for any given individual patient case or infusion regimen. Automated drug delivery systems can provide more precise predictions of the time required for the plasma or effect-site concentration to decrease to any desired concentration, based on the actual drug dosing in the individual patient, which provides the clinician with guidance for the most appropriate time to terminate the infusion.

Context-sensitive decrement times focus on the role of pharmacokinetics in recovery from anesthesia. Pharmacodynamics plays an important role in recovery as well. Bailey[113] used integrated pharmacokinetic-pharmacodynamic models to define the *mean effect time* as the average time to responsiveness after maintenance of anesthesia at the 90% probability of unresponsiveness. The mean effect time demonstrates that when drugs have a very shallow concentration-versus-response relationship, concentrations must decrease by a significant fraction to provide adequate emergence, which delays recovery from anesthesia. In contrast,

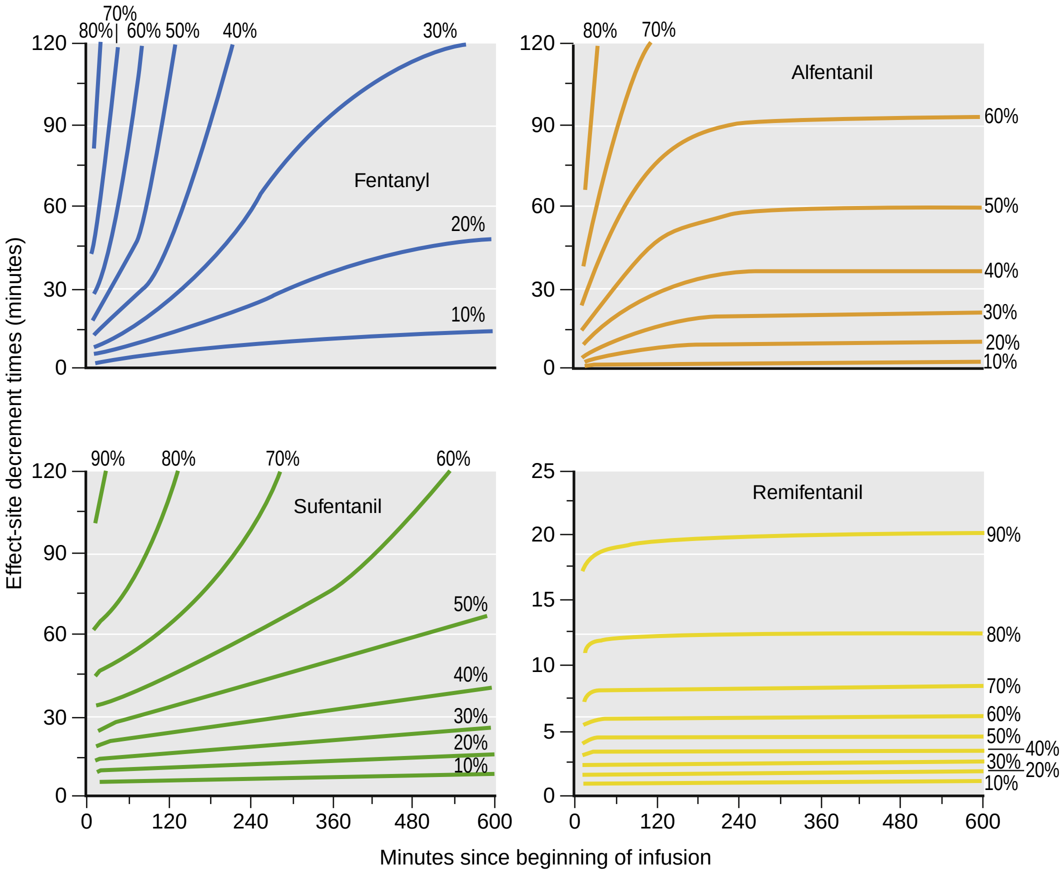

Fig. 26.21 Context-sensitive effect-site decrement times for alfentanil, fentanyl, sufentanil, and remifentanil showing the time required for decreases of a given percentage (labeled for each curve) from the maintained effect-site concentration after termination of the infusion.

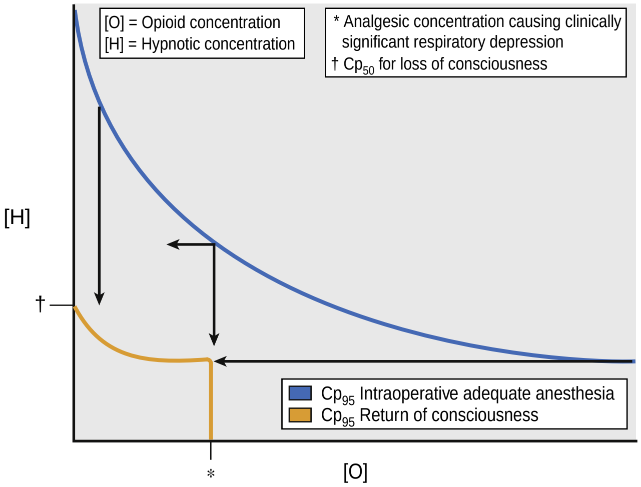
recovery is hastened by a steep concentration-versus-response relationship, in which emergence from anesthesia occurs after a relatively small fractional decrease in concentration. Most intravenous hypnotics have a moderately steep concentration-versus-response relationship.

Pharmacodynamic drug interactions also play a role in recovery from anesthesia. Interaction relationships predict that the same anesthetic state can be achieved by different ratios of two drugs. One way of selecting the best ratio might be the combination that offers the most rapid recovery. For example, when an opioid is combined with a hypnotic, the rate of recovery from anesthesia depends on the opioid and hypnotic concentrations, the rate of decrease in both drug concentrations, and the relative synergy between them for loss of response to noxious stimulation (i.e., the state maintained during anesthesia) versus the relative synergy for loss of consciousness. Although the time course of decreases in opioid and hypnotic concentrations can be approximately described by their respective context-sensitive decrement times for both drugs (Fig. 26.22; see Fig. 26.15]), the influence of relative synergy for different endpoints must be captured by separate models of the interaction of the drugs for adequate anesthesia and emergence from anesthesia.

Vuyk and coworkers[54] modeled the predicted time to awakening from adequate anesthesia when propofol is combined with fentanyl, sufentanil, alfentanil, or remifentanil. Their calculations took into account the interaction between propofol and these opioids to provide adequate anesthesia and the interaction between propofol and opioids on consciousness levels on emergence from anesthesia (Figs. 26.23 and 26.24). Recovery times vary with the choice of opioid and the relative balance of opioid and



[O] = Opioid concentration

Fig. 26.22 Interaction between hypnotics and opioids for the prevention of movement after a noxious stimulus and for awakening and adequate spontaneous ventilation at the end of a surgical procedure. The time to recover at the end of a procedure is dependent on the concentration of both drugs used during surgery and the time for both to decrease below that required for consciousness and adequate spontaneous ventilation (i.e., their context-sensitive decrement times).

propofol during maintenance of anesthesia. For example, the upper left of Fig. 26.23 simulates the emergence from a propofol-fentanyl anesthetic of 15-minute duration. The simulations assume a steady concentration of fentanyl and propofol throughout the anesthesia, similar to the underlying assumption of context-sensitive decrement times. The lowest curve on the response surface is the interaction curve between fentanyl and propofol; it ranges from no fentanyl and 12 μg/mL of propofol on the left to 5.33 ng/mL of fentanyl and 1.8 μg/mL of propofol on the right. In theory, any point along this curve would ensure maintenance of equivalent depth of anesthesia. When the infusion is turned off after 15 minutes of anesthesia, the concentrations of both drugs decrease. The decreasing concentrations of propofol and fentanyl when the infusion is turned off can be found by the upward lines drawn from different points on the interaction curve, with the distance away from the lower plane representing time. Taken together, these upward lines represent a *recovery surface*. The blue line drawn on the recovery surface shows the points at which the fentanyl-propofol interaction model predicts emergence.

After 15 minutes of maintaining 1.8 μg/mL of propofol and 5.33 ng/mL of fentanyl (right margin of the interaction curve), approximately 12 to 17 minutes is needed for the concentrations of both drugs to decrease sufficiently to permit emergence (see Fig. 26.23). However, if one maintains concentrations of 3.5 μg/mL of propofol and 1.5 ng/mL of fentanyl (toward the middle of the interaction curve),

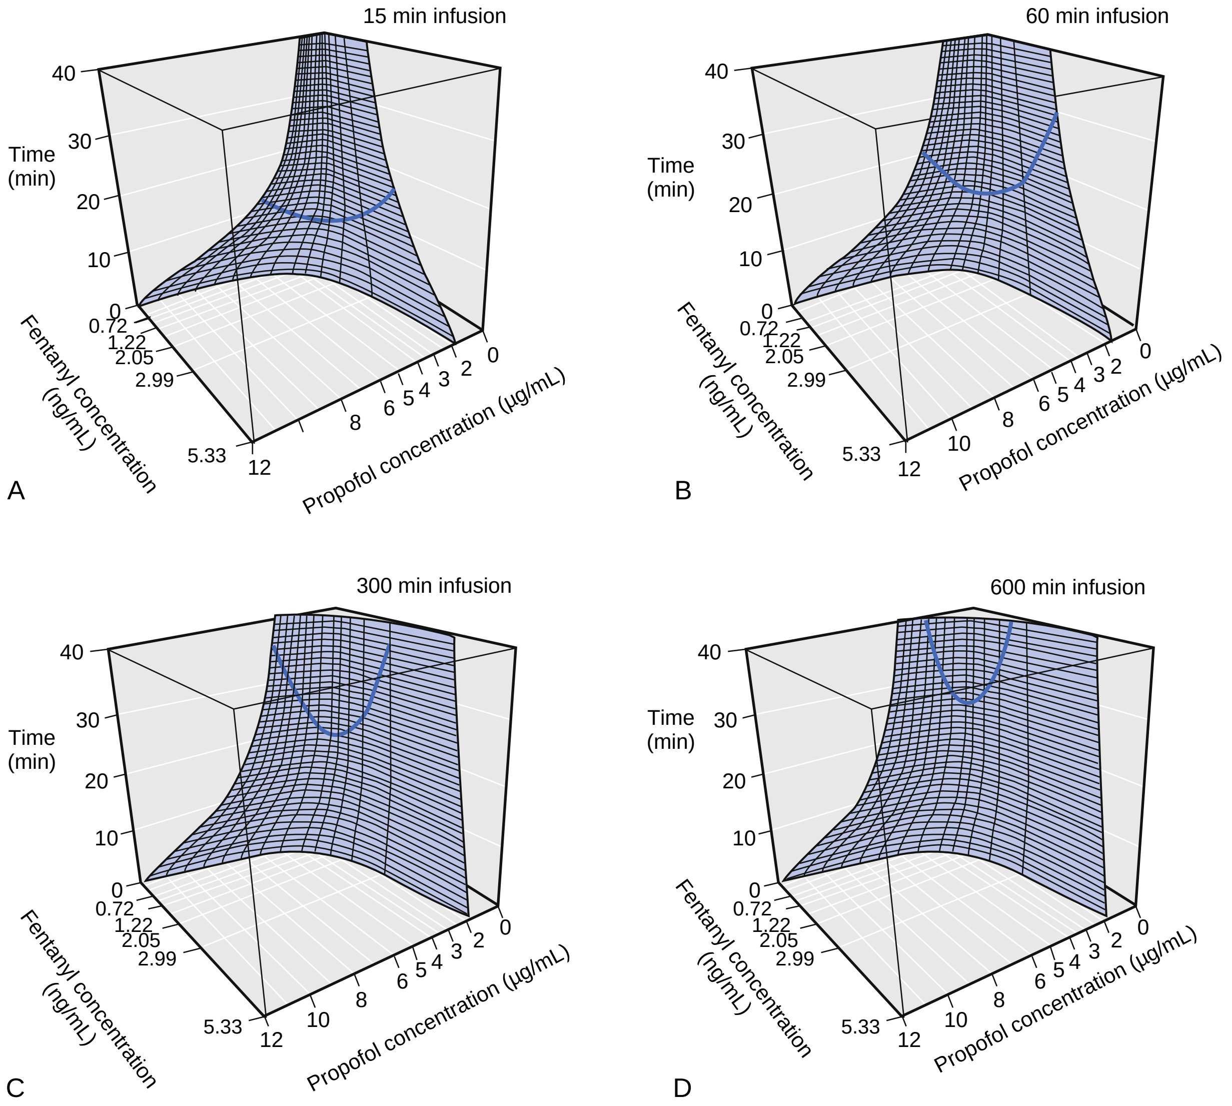

Fig. 26.23 Simulation of the interaction of propofol and fentanyl in preventing a somatic response at skin incision and time to recovery. On the *x* axis is the fentanyl concentration, and on the *y* axis is the propofol concentration. The *blue curve* in the lower plane shows the propofol-fentanyl interaction required to provide adequate anesthesia. When the infusion is turned off, the concentrations of each drug decrease, as shown on the *z* axis. The *blue curve* drawn on the recovery surface shows the time to emergence from anesthesia for combinations of fentanyl and propofol after an anesthetic of 15 minutes' (A), 60 minutes' (B), 300 minutes' (C), and 600 minutes' (D) duration. The optimal combination for the most rapid recovery is a propofol concentration of 3.0 to 3.5 μg/mL, combined with 1.5 ng/mL fentanyl. As the concentration of propofol or fentanyl increases, the time for recovery increases. In addition, the longer the duration of drug infusion, the longer recovery takes, especially if the optimal combination is not used. (Modified from Vuyk J, Mertens MJ, Olofsen E, et al. Propofol anesthesia and rational opioid selection. Determination of optimal EC50-EC95 propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. *Anesthesiology*. 1997;87:1549–1562.)

then emergence can be expected only 8 minutes after the infusions are turned off. Examination of the curves for 60, 300, and 600 minutes of propofol-fentanyl anesthesia suggests that the fentanyl target concentration that provides the most rapid emergence is approximately 1.0 to 1.5 ng/mL, which requires a propofol concentration of approximately 3.0 to 3.5 μg/mL to maintain adequate anesthesia. In similar simulations, Vuyk and colleagues demonstrated that maintaining alfentanil and sufentanil concentrations in excess of the analgesic range (i.e., approximately 80 ng/mL for alfentanil and 0.15 ng/mL for sufentanil) is of little clinical benefit and can be expected to delay recovery from anesthesia. A second conclusion from these simulations is that if the patient demonstrates inadequate anesthesia, increasing the hypnotic concentration rather than increasing the opioid concentration beyond the analgesic range is preferable, so as to prevent prolongation of recovery.

The situation is different for remifentanil because of its unusual pharmacokinetic properties (see Fig. 26.24). When a remifentanil infusion is terminated, the extraordinarily fast clearance of remifentanil results in a very rapid offset of opioid drug effect. The lower plane again shows equivalent anesthetic states during maintenance with remifentanil and propofol (see Fig. 26.24). High doses of remifentanil permit a modest reduction in the dose of propofol needed for adequate anesthesia.[114] However, the recovery surfaces show that high doses of remifentanil, with a modest reduction in the propofol dose, permit considerably faster emergence

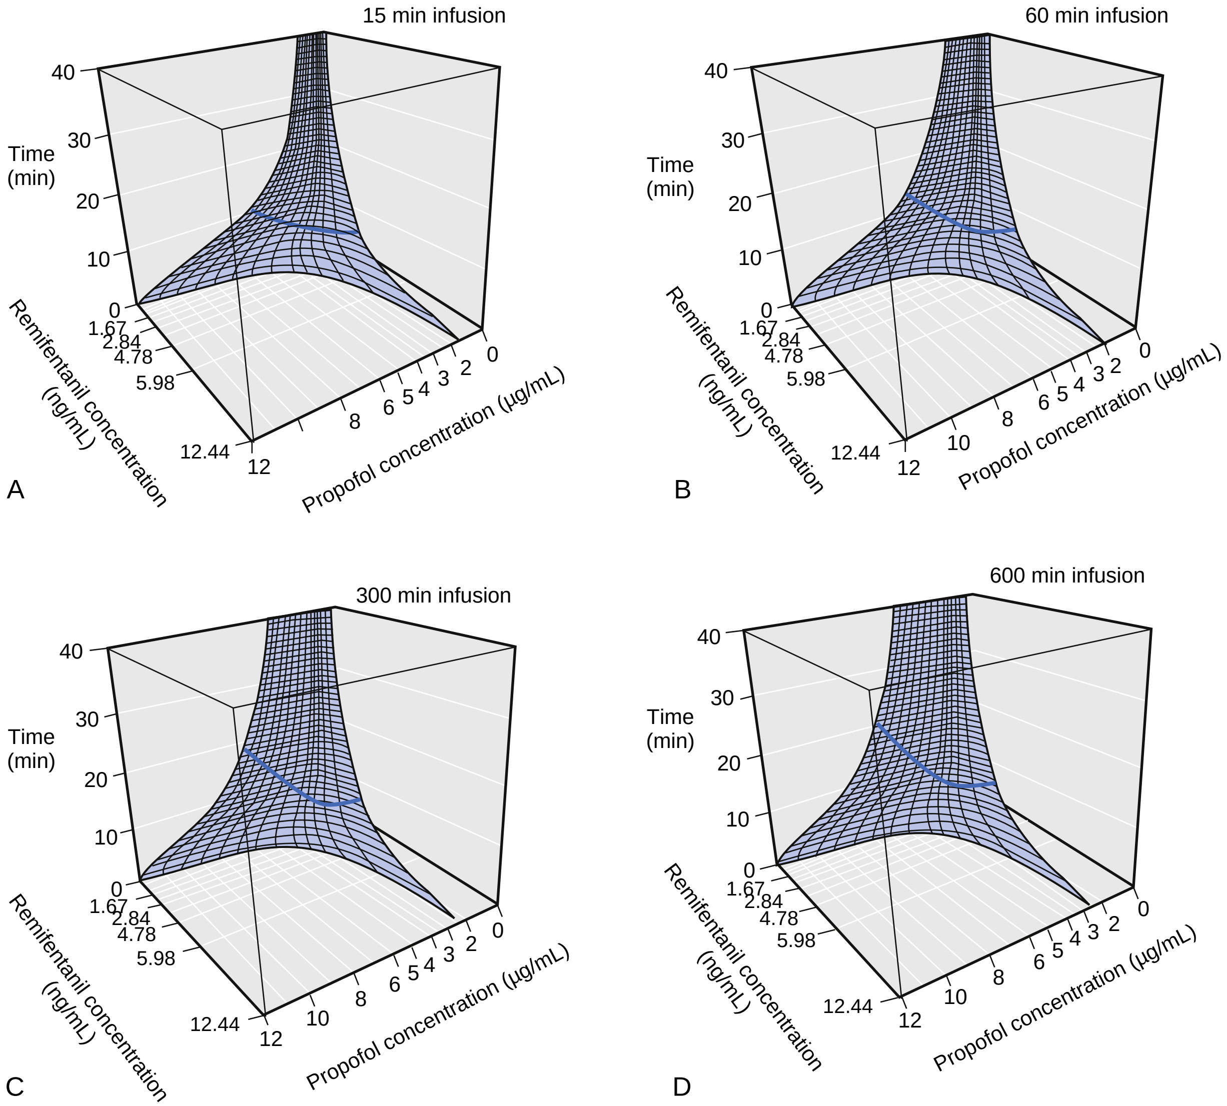

Fig. 26.24 Simulation of the interaction of propofol and remifentanil in preventing a somatic response at skin incision and time to recovery. The remifentanil concentration is on the *x* axis, and the propofol concentration is on the *y* axis. The *blue curve* in the lower plane shows the propofol-remifentanil interaction required to provide adequate anesthesia. When the infusion is turned off, the concentrations of each drug decrease, as shown on the *z* axis. The *blue line* drawn on the recovery surface shows the time to emergence from anesthesia for combinations of remifentanil and propofol after an anesthetic of 15 minutes' (A), 60 minutes' (B), 300 minutes' (C), and 600 minutes' (D) duration. With remifentanil, the optimal combination is a propofol concentration of 2.5 μg/mL and with remifentanil, 5 to 7 ng/mL. In addition, increasing the duration of the infusion has minimal impact on recovery time if the optimal dose of remifentanil is not used. However, if the propofol dose is increased, then recovery is prolonged. (Modified from Vuyk J, Mertens MJ, Olofsen E, et al. Propofol anesthesia and rational opioid selection. Determination of optimal EC50-EC95 propofol-opioid concentrations that assure adequate anesthesia and a rapid return of consciousness. *Anesthesiology*. 1997;87:1549–1562.)

Fig. 26.25 On-line advisory displays including characteristics of drug behavior and interaction. The SmartPilot (Dräger, Lübeck, Germany) *(upper display)* is a two-dimensional display that shows the effect-site concentrations of combined drugs (opioids and intravenous or inhalation hypnotics), based on pharmacokinetic models and the resulting anesthetic effect and on pharmacodynamic models. Grey shaded areas indicate different levels of anesthesia. The *orange point* indicates the current combination of effect-site concentrations; the *white line* shows the retrospective concentrations; and a 10- and 15-minute prediction is marked by a *black point* and *arrow*—already calculated during presetting of delivery. Event markers may be set to show specific states of the patient related to the level of anesthesia. The time-based real-time curves, trends, and prediction of effect-site concentrations of individual drugs, resulting anesthetic effect (noxious stimulus response index [NSRI]), correlated bispectral index (BIS), vital signs, and event markers are shown as reference for interpretation. The Medvis display (Medvis, Salt Lake City, Utah) *(lower display)* shows a real-time visualization of anesthetic using pharmacokinetic and pharmacodynamic models to predict drug effect-site concentrations and drug effects in the past, current time, and 10 minutes into the future. Drug doses as boluses and infusions are administered via a separate data interface or user interface. Drugs are categorized according to sedation *(top plot)*, analgesia *(middle plot)*, and muscle relaxation *(bottom plot)*. Effects are depicted as a population-based probability of unconsciousness *(top plot)*, no response to tracheal intubation *(middle plot)*, and no twitch response to a train of four stimulus *(bottom plot)*. In addition, a second pharmacodynamic endpoint, POST-OP ANALG, represents a guideline therapeutic window for postoperative pain. Synergistic interactions of sedative-hypnotics and analgesics are shown by the *white curves* in the plot. For example, the top plot shows that with only propofol, the probability of unconsciousness is between 50% and 95% *(yellow curve)*, but because propofol interacts with the opioids, the probability of unconsciousness is greater than 95% *(white curve)*. Similarly, propofol potentiates the effect of the opioids in the middle plot.

from anesthesia. For example, it takes approximately 12 minutes to awaken from 600 minutes of anesthesia maintained with 3 μg/mL of propofol and 2.5 ng/mL of remifentanil (see Fig. 26.24*D*). On the other hand, if the remifentanil concentration is increased to 5 ng/mL, then the propofol concentration can be reduced to between 2 and 2.5 μg/mL, and emergence can be anticipated within 6 minutes of discontinuation of the infusions. One might be concerned that such a technique places patients at increased risk for awareness because a propofol concentration of 2 μg/mL is below the C_{50} value for wakefulness.[115] Therefore combining such a technique with intraoperative EEG monitoring to assess anesthetic adequacy is reasonable.[21,115]

DISPLAYING PHARMACOLOGIC INFORMATION

Integrating all sources of pharmacologic information including drug interaction together with measurements of patient response to a specific drug dose might offer a powerful advisory tool to depict the complete dose-response relationship of multiple drugs, thereby optimizing drug administration and improving patient care.[116,117] For example, Fig. 26.25 shows a drug interaction advisory display.

Intravenous Infusion Devices and Technologies

MANUAL INTRAVENOUS INFUSION

When an infusion of an intravenous anesthetic is administered, the infusion regimen can be controlled by a variety of mechanisms varying from the simple Cair clamp or Dial-a-Flo (Abbott Laboratories) to complex computer-controlled infusion pumps. Simplicity of mechanical design, however, is not necessarily correlated with ease of use, which has prompted ongoing advances in infusion device technology over the past decades.

Infusion devices can be classified as either controllers or positive displacement pumps. Explicit in their title, controllers contain mechanisms that control the rate of flow produced by gravity, whereas positive displacement pumps contain active pumping mechanisms.

The most commonly used pumps for administration of intravenous anesthetics are positive displacement syringe pumps that use a variety of mechanisms. These pumps have acceptable accuracy and have several features that make them particularly suitable for anesthetic delivery. An important advance has been the introduction of a calculator feature within the pump so that the clinician can input the weight of the patient, the drug concentration, and the infusion rate in dose/unit weight/unit time and the pump will then calculate the infusion in volume/unit time. These pumps also permit simple application of a staged infusion scheme by allowing an initial dose and a maintenance infusion rate to be programmed into the pump. Numerous syringe pumps also include automated recognition of syringe size. Further enhancements are drug libraries by class of drug, suggested dosing schemes, and maximal dosing alerts. These modest advances in pump technology and design enable intravenous anesthetics to be conveniently and safely delivered.

In addition to the pumps, the complete intravenous delivery systems' hardware must perform perfectly,[5] which means that the correct amount of drug should be delivered to the venous circulation in each unit of time. When the drug administration set has too large a *deadspace*, the actual delivery rate can be altered, depending on the flow rate of coadministered fluid.[118] The use of an antireflux valve is certainly advisable to prevent flow of the medication backward into the intravenous fluid bag rather than into the patient. Other factors include excessive compliance within the administration system (in the syringe plunger or in the administration lines) and the use of syringes with suboptimal lubrication, causing the plunger to advance in small jumps when infusion rates are slow; that is, with

TABLE 26.5 Manual Infusion Schemes

	ANESTHESIA		SEDATION OR ANALGESIA	
Drug	**Loading Dose (μg/kg)**	**Maintenance Infusion (μg/kg/min)**	**Loading Dose (μg/kg)**	**Maintenance Infusion (μg/kg/min)**
Alfentanil	50-150	0.5-3	10-25	0.25-1
Fentanyl	5-15	0.03-0.1	1-3	0.01-0.03
Sufentanil	0.5-5	0.01-0.05	0.1-0.5	0.005-0.01

Ketamine	1500-2500	25-75	500-1000	10-20
Propofol	1000-2000	50-150	250-1000	10-50
Midazolam	50-150	0.25-1.5	25-100	0.25-1
Methohexital	1500-2500	50-150	250-1000	10-50
Dexmedetomidine			0.5-1 over 10 min	0.2-0.7

*For analgesia or during sedation, an initial loading dose of remifentanil should not be given because its very rapid onset may result in apnea or muscle rigidity. After the loading dose, an initially high infusion rate to account for redistribution should be used and then titrated to the lowest infusion rate that will maintain adequate anesthesia or sedation. When using opiates as part of a nitrous-narcotic technique or for cardiac anesthesia, the dosing scheme listed under anesthesia is used. When the opiate is combined as part of balanced anesthesia, dosing listed for analgesia is needed.

small patients, low target concentrations, drug solutions of high concentration, or large-volume syringes.[5]

Manual intravenous drug delivery consists of a combination of a bolus dosage and a continuous infusion, as explained earlier when discussing the pharmacokinetic considerations. Table 26.5 offers recommendations for delivering intravenous anesthetics via conventional infusion pumps based on integrated pharmacokinetic-pharmacodynamic models. Ultimately, the adequate rate of drug administration is based on observation and examination. Individual patients vary significantly in their response to a given drug dose or concentration; therefore titrating to an adequate drug level for each individual patient is essential. Drug concentrations required to provide adequate anesthesia also vary according to the type of surgery (e.g., superficial surgery vs. intraabdominal surgery). Drug concentration requirements are often smaller during the end phase of surgery; therefore titration often involves judicious reduction of the infusion rate toward the end of surgery to facilitate rapid recovery.

If the infusion rate is insufficient to maintain adequate anesthesia, then both an additional loading (bolus) dose and an increase in infusion are required to increase the plasma (biophase) drug concentration rapidly. Various interventions also require larger drug concentrations, usually for brief periods (e.g., laryngoscopy, endotracheal intubation, skin incision). Consequently, the infusion scheme should be tailored to provide peak concentrations during these brief periods of intense stimulation. An adequate drug level for endotracheal intubation is often achieved with the initial loading dose; however, for procedures such as skin incision, an additional bolus dose may be necessary.

Infusion schemes (see Table 26.5) do not approach the convenience and precision of use associated with the delivery of an inhaled anesthetic via a calibrated vaporizer, particularly when the user is still required to calculate volume infusion rates (mL/hr) from the mass-based infusion rates given in the infusion schemes. The use of "calculator" pumps helps to simplify the task of the anesthesiologist. At start-up the user is required to input the weight of the patient and the drug concentration. Thereafter, the pumps are able to accept as input mass-based rates, from which they calculate and implement volume infusion rates. The level of convenience and precision of vaporizers can however be achieved by using TCI devices, such as the commercially available TCI pumps.

COMPUTER-CONTROLLED DRUG DELIVERY

As discussed in the introduction of this chapter, optimal patient-individual dosing may be achieved by the application of pharmacokinetic and pharmacodynamic principles. Using the dose-response relationship, drug titration should be performed as close as possible to the drug effect. Titrating to a specific effect or, if not possible, a specific effect-site concentration offers advantages. Because the effect-site or plasma concentrations are not continuously measurable online for most intravenous anesthetics (in contrast to inhaled anesthetics), a drug model using a computer that continuously updates the anesthetic administration rate to maintain an estimated drug effect or drug concentration is required (Fig. 26.26).

If a specific plasma or effect-site concentration is titrated, then this technique is called TCI. TCI is a *closed-loop control* system. The history of the development of TCI systems has recently been summarized.[119] In these systems the clinician serves as the *human controller* in the loop and, as a consequence, the control actions are intermittent and irregular in time.[120] Control theory is increasingly being applied in the development of computer-controlled drug delivery systems, among others in anesthetic closed-loop control applications. The aim of computer-controlled closed-loop systems is to formalize this process of observation and intervention to provide fine-tuned and more accurate control. Such systems use a near continuous signal of drug effect, calculate the error between the observed value and the set point value (selected by the user), and use this error figure in an algorithm to make frequent and regular adjustments to drug administration rates. Some computer-controlled drug delivery systems try to predict the future drug effect to make appropriate adjustments well in advance.[120]

TARGET-CONTROLLED INFUSION

Devices

The development of microprocessor-controlled syringe pumps and a better understanding of the dose-response relationship have enabled the development of TCI systems. A TCI is a computer- or microprocessor-controlled system that aims to achieve a user-defined estimated drug concentration in a body compartment or tissue. A clinician using a TCI system to administer an anesthetic drug is thus able to set and adjust a desired drug concentration, usually referred to as the *target concentration*, based on clinical observation of the patient or measurement of drug effect. Multicompartment pharmacokinetic-pharmacodynamic models are used by TCI systems to calculate the infusion rates required to achieve the target concentration (see Fig. 26.4). A computer or microprocessor is required to perform the complex calculations and to control the infusion pump. Typically, plasma or effect-site concentrations are targeted.[3]

TCI systems in use today still apply the theoretical approach described by Kruger-Thiemer[121] to achieve and maintain a steady-state blood concentration of a drug whose pharmacokinetic can be described by a multicompartment model. This approach was first clinically implemented by Schwilden.[7] The infusion schemes used, better known as bolus-elimination-transfer (BET) schemes (see Fig. 26.4), were initially designed for two-compartment models. Briefly, the infusion starts with an initial bolus of drug required to achieve the initial target concentration. Second, an infusion is administered to replace drug lost by elimination. Since the elimination rate constant is fixed, the amount of drug eliminated in each unit of time is proportional to the plasma concentration; accordingly, at steady-state plasma concentrations, drug removal by elimination can be compensated for by a constant rate infusion. Third, a second infusion is administered to replace drug distributed or transferred to peripheral tissues. The amount redistributed exponentially declines over time as the gradient between the central compartment and the peripheral compartment decreases. Replacing distributed drug requires an infusion at an exponentially declining rate to replace drug *lost* from the central compartment by distribution until steady state.[4]

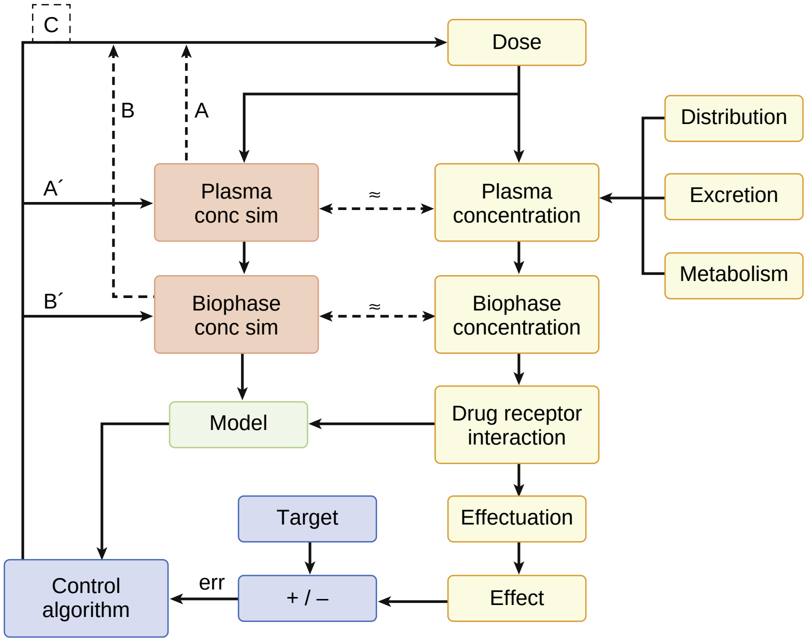

Fig. 26.26 Schematic representation of the pharmacokinetic and pharmacodynamic processes determining the relationship between administered doses and resulting effect intensity of a drug *(yellow)*. Pharmacokinetic factors such as distribution, metabolism, and/or excretion determine the relationship between drug dose and drug concentration in the biophase. In the biophase, the drug interacts with the receptor, and the pharmacologic effect is accomplished via effectuation processes. Target-controlled infusion (TCI) will use a model to estimate the plasma or biophase drug concentration *(red)*, and will calculate the dose needed to approach a target concentration in plasma *(A)* or biophase/effect-site *(B)*. Computer-controlled, closed-loop feedback measures the error between the effect and the target effect to control the dose administration *(blue)*. Better closed-loop performance can result if, rather than using the dose as a direct actuator, the *simulated* variable of a TCI system is used as actuated variable *(A/A´, B/B´)*. The TCI system then compensates for part of the complexity of the dose-interaction relationship. Advanced control algorithms may take into account a continuously updated model of the interaction *(light green)*. (Modified from Struys M, de Smet T. Principles of drug actions: target-controlled infusions and closed-loop administration. In: Evers AS, Maze M, Kharasch ED, eds. *Anesthetic Pharmacology: Basic Principles and Clinical Practice.* Cambridge: Cambridge University Press; 2011:103–122. Used with permission.)

BET schemes have some disadvantages such as the requirement of a no-drug status before infusion, which disables a change in the target concentration. In addition, more recent research concluded that the pharmacokinetics of most anesthetics is better described using a three- instead of a two-compartment model. Lastly, as previously discussed in this chapter, the plasma is not the site of drug effect. Consequently, effect compartment–controlled TCI algorithms were developed.[29] During the 1990s, various computer-based TCI prototypes were developed by researchers at Stanford (STANPUMP, California), Stellenbosch (STELPUMP, South Africa), Duke (computer-assisted continuous infusion [CACI], North Carolina), and Ghent (RUGLOOP, Belgium) universities. Groups in Erlangen, Germany, and Leiden, The Netherlands, produced software able to simulate pharmacokinetic trajectories (IVA-SIM and TIVA Trainer, respectively). Finally, the Diprifusor (AstraZeneca, London) became the first commercially available TCI pump. It was based on a prototype from the Kenny group[122] and was able to control a set plasma target concentration using specific prefilled syringes from AstraZeneca. Although the technology never became available in the United States,[8] this TCI pump was the first breakthrough in an attempt to optimize drug administration in daily clinical practice in many countries. More recently, various companies have commercialized more flexible *open TCI* pumps capable of administering multiple drugs in both plasma and effect compartment–control mode (Fig. 26.27).[8,119]

Effect compartment–control requires a rate constant that accurately describes the rate of equilibration between plasma (Fig. 26.28*A*) and effect-site concentrations (Fig. 26.28*B*). The benefits of effect compartment–controlled TCI were demonstrated for propofol by Wakeling and associates[123] and Struys and associates.[47] This mode is commonly used throughout Europe.

A detailed description of the history of the development of TCI and of the development and availability of TCI devices was published in 2016.[8,124]

Evaluation of Target-Controlled Infusion Delivery

Acceptance of target-controlled drug delivery of intravenous anesthetics requires evaluation of accuracy (defined as the difference between predicted and measured concentrations) and outcomes among patients in whom automated drug delivery has been used. The inaccuracies associated with pharmacokinetic model–driven devices are attributed to possible problems with the software and hardware, and more importantly to pharmacokinetic variability (Fig. 26.29).

Inaccuracy in the software results from incorrect mathematic implementation of the pharmacokinetic model. Computer simulations can be used to test the infusion rates as calculated by a software program, and thus software errors are fairly simple to identify and correct.[125] Inaccurate drug delivery from the infusion pump (i.e., failure to correctly infuse the amount intended by the system) infrequently

occurs with present syringe-pump technology and contributes little to the overall inaccuracy of these devices.[126] The aforementioned safety review identified only two company reports of problems with TCI devices that were attributable to software programming errors, neither of which caused actual patient harm.[127]

The major cause of inaccuracy is biologic variability, of which there are two sources: (1) the pharmacokinetic model is always wrong,[106] and (2) the pharmacokinetics of the individual patient are not as programmed into the model. The pharmacokinetic model is always wrong because individuals are far more complex than implied by simple compartment models,[106] and no model can precisely predict the concentrations, even if the pharmacokinetic parameters in the individual were known with absolute precision. However, even if the pharmacokinetic model truly reflected the underlying biologic variables, the parameters of the model would be average parameters for the population and not the exact parameters of the patient. Even if the parameters were modified to reflect the influence of demographic factors such as age, gender, hypovolemia, and coadministration of other drugs, they would still deviate from the true pharmacokinetic parameters in the individual. Thus biologic variability fundamentally precludes the possibility of precisely achieving the desired target concentration when automated drug delivery devices are used. Realizing that biologic variability always exists, no matter how drugs are given, and that this same biologic variability affects all methods of drug delivery is important. Nonetheless, the variability with TCI devices will always be less than the variability observed after a single bolus injection.[128] The performance of computer-controlled drug administration

must be interpreted in terms of the therapeutic expectations of the clinician. Possible goals include accurately producing a desired concentration in plasma, precisely titrating the plasma drug concentration, achieving the desired drug effect, and producing the desired time course of drug effect. Over the past decade, investigators have addressed each of these goals and have refined the performance of automated drug delivery devices accordingly.

The ability of an automated drug delivery system to rapidly achieve and then maintain a selected target concentration is a logical measure of the performance of such a device. The difference between the measured and target concentrations can be expressed in several ways. Classic graphic representations are X-Y plots depicting predicted versus measured blood (plasma) drug concentrations (Fig. 26.30) or the relationship of the measured and predicted drug concentration versus time of administration (Fig. 26.31). Numerically, the primary concern is how far the measured concentration is from the predicted one; this relationship is now most frequently described in terms of performance errors, which is the difference between measured and target concentrations as a percentage of the desired target—for example, [(measured − target) ÷ target × 100%].[129] The median value of the performance error for a patient or population is referred to as the median performance error (MDPE) and represents the average overshoot or undershoot of the system. The median absolute performance error (MDAPE) is the median of the absolute values of all performance errors. The MDAPE is commonly used as a measure of the inaccuracy of an automated drug delivery device. An MDAPE of zero is perfect performance, and an MDAPE of 20% means that one half the plasma concentrations will be within 20% of the target and one half will be outside that range. A further assessment of accuracy is whether the system maintains a stable target concentration, which is best measured by the wobble of the system. Varvel and colleagues[129] asked a group of clinicians to evaluate the performance of automated drug delivery devices and demonstrated that the MDAPE best predicted the adequacy of performance of the automated delivery device, as judged by experienced clinicians.

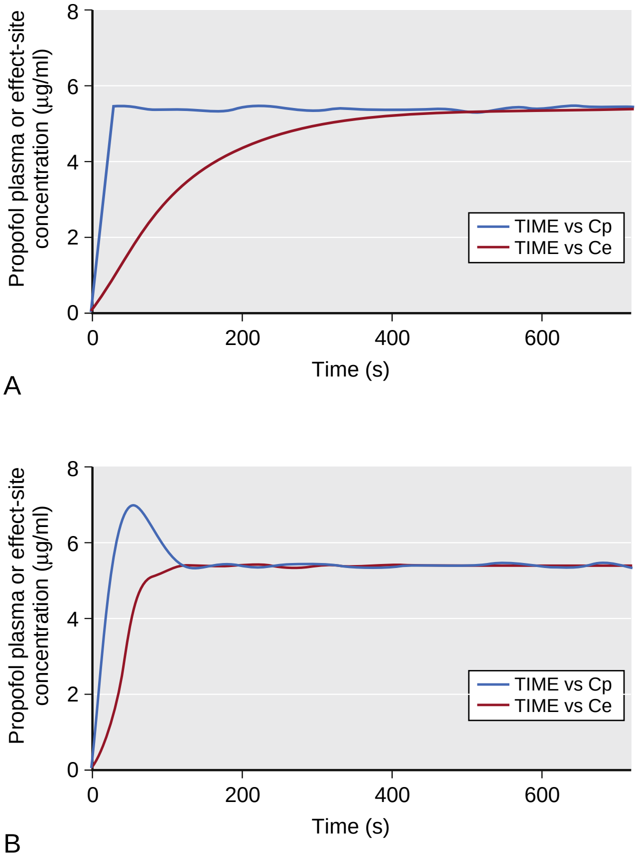

Fig. 26.28 Simulation of propofol plasma (A) versus effect compartment–controlled (B) target-controlled infusion.

As observed earlier, expecting all performance errors to be zero is not reasonable. However, it would be desirable if positive and negative errors offset each other so that the MDPE of an automated drug delivery device were 0%. The MDPE does not indicate the range of performance errors (because positive and negative performance errors offset each other), but it does indicate whether the plasma concentrations achieved with the device tend to overshoot (+MDPE) or undershoot (−MDPE) the desired target.

Many groups have evaluated the accuracy of many different pharmacokinetic sets for virtually all the intravenous hypnotics and analgesics. Most studies have involved healthy volunteers or lower-risk patients undergoing procedural sedation or anesthesia, and in these settings the authors have studied adult models for propofol,[13,31,130-137] midazolam,[138] ketamine,[139] dexmedetomidine,[140,141] fentanyl,[142-144] alfentanil,[67,145-147] sufentanil,[138,148,149] and remifentanil.[150,151] Pediatric models for propofol have also been evaluated.[152-155]

Few studies have been performed in the intensive care unit (ICU) setting. The performance of the Marsh model for propofol sedation in different adult populations has however been studied.[156,157]

Based on many of these studies, the expected predictive performance of such pharmacokinetic models, at best, tends to be around 20% to 30% MDAPE.

Model Selection for Target-Controlled Infusion: Adult Propofol Models

For most intravenous drugs, various multicompartment pharmacokinetic-pharmacodynamic models have been published. The pharmacokinetics of propofol have been the most frequently tested (see Fig. 26.6) of all anesthetic drugs. Coetzee and coworkers compared the accuracy of some of the models published before 1995 and found that propofol TCI using the model published by Marsh and coworkers resulted in acceptable performance (MDPE −7%; MDAPE 18%).[130]

The Marsh model was incorporated in the first commercially available TCI system (Diprifusor). Clinical studies using this plasma-controlled TCI system showed that the technique and model were clinically useful in various clinical situations.[158-162] The major drawback of the Marsh model is the lack of effect compartment information and

The performance of compartmental and physiologically based recirculatory pharmacokinetic models for propofol. A comparison using bolus, continuous, and target-controlled infusion data. *Anesth Analg.* 2010;111:368–379. Used with permission.)

the fact that weight is the only covariate. Later, Schnider and coworkers[163,164] evaluated age, height, weight, and lean body mass as covariates in a new combined pharmacokinetic-pharmacodynamic three-compartment model. The large variability of the study population (age 18-81 years, weight 44-123 kg) provides a wide applicability of the model. Several validation studies rated this model accurate under various conditions. For example, Masui and colleagues[13] compared the measured propofol plasma concentrations with the predictions of four published models and revealed bias in all three compartment models during the bolus and short infusion regimens (see Figs. 26.30 and 26.31). During long infusions, a worse measured/predicted propofol plasma concentration at higher concentration was observed for the Marsh[152] and Schüttler[165] models than for the two other models. Less biased measured/predicted propofol plasma concentration was found for all models during TCI. In the bolus group, after 1 minute, a clear overprediction was observed for all three-compartment models for the entire 5-minute period; however, this initial error resolved after 4 minutes in the Schnider model. During the bolus and short infusion conditions, the Marsh model demonstrated worse MDPE and MDAPE when compared with the other models. During short infusion, MDAPE for the Schnider and Schüttler models was better. All models showed similar MDPE and MDAPE during TCI simulations. During long infusion, the Marsh and the Schüttler models underestimated the higher plasma concentrations. Interestingly, the physiologically based recirculatory model developed by Upton and coworkers[14] did not reveal a better description of the pharmacokinetic time course. The Schüttler model has a major practical drawback; it defined the infusion characteristics, being bolus or infusion, as a significant covariate, thereby discouraging TCI applicability.

An additional drawback of the Schnider model is the use of lean body mass as calculated using the equation developed by James.[12] The quadratic behavior of the lean body mass function makes it invalid (negative values!) when used in patients who are very obese. Therefore as changing population demographics such as obesity might influence the pharmacokinetics of propofol, models should ideally be applicable to a broad range of population demographics

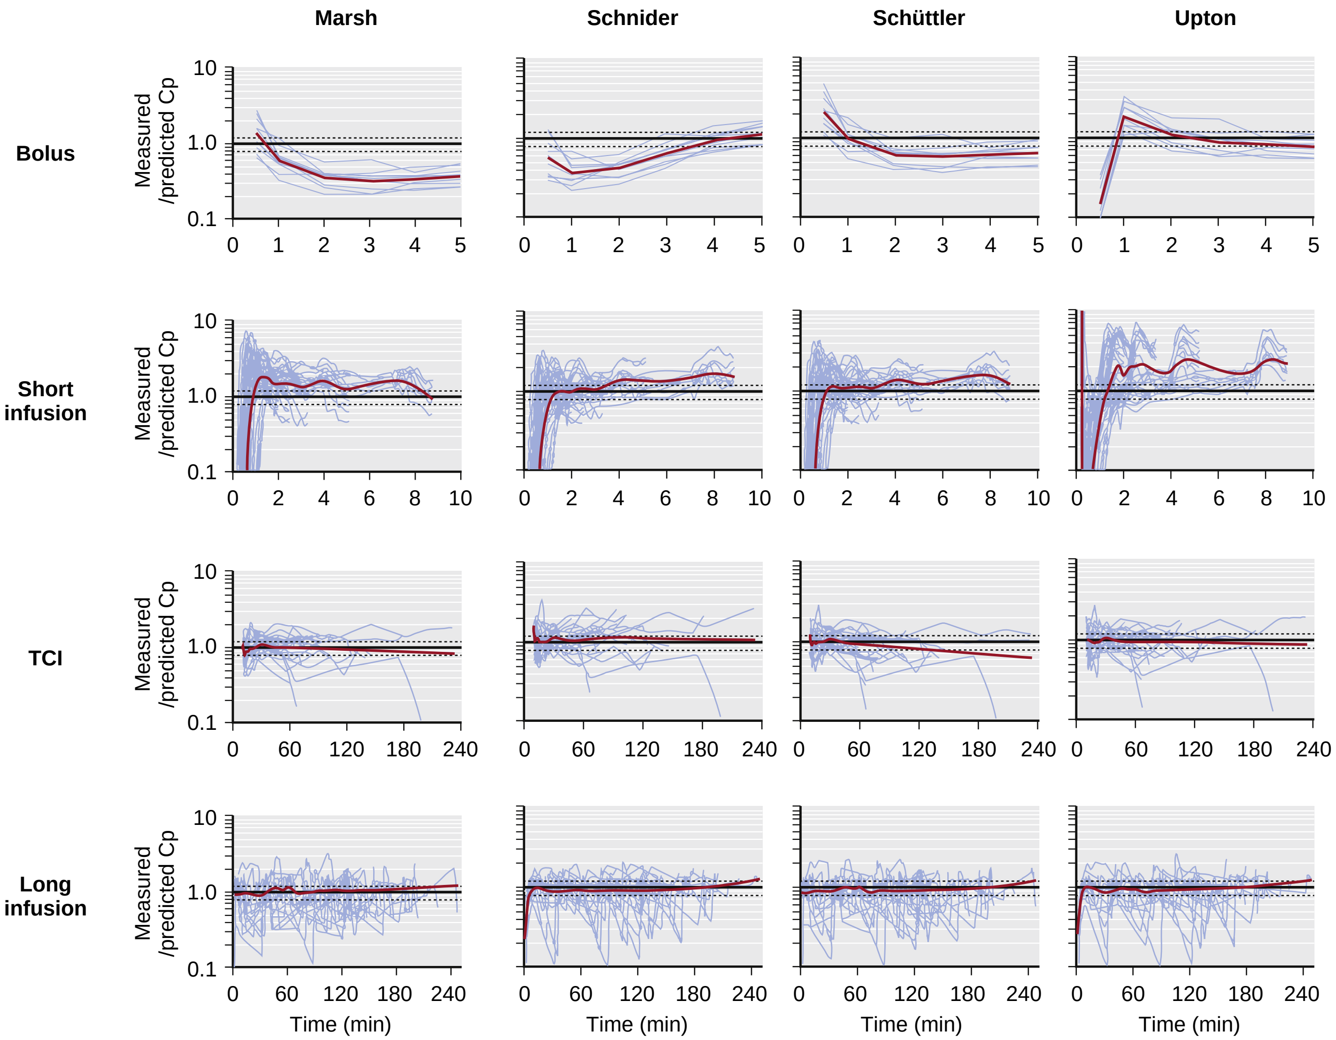

Fig. 26.31 Time course of the measured/predicted concentration relationship versus time of drug administration. The *dotted lines* indicate an acceptable range of measured/predicted plasma drug concentration *(Cp)*. The *red line* indicates the Friedman Super Smoother curve for the population data. (From Masui K, Upton RN, Doufas AG, et al. The performance of compartmental and physiologically based recirculatory pharmacokinetic models for propofol: a comparison using bolus, continuous, and target-controlled infusion data. *Anesth Analg*. 2010;111:368–379. Used with permission.)

before being used in clinical practice. One potential solution to the problem of scaling for size in obese patients is the application of allometric scaling. When using allometric scaling, growth and development can be studied using classic covariates (e.g., weight, age, sex). Size is the primary covariate and can be referenced to a 70-kg person with allometric scaling using a coefficient of 0.75 for clearance and 1 (one) for volume. Anderson and Holford[166] promote this approach because the use of these coefficients is supported by fractal geometric concepts and observations from biologically diverse areas.[167]

Cortinez and coworkers[168] derived a population pharmacokinetic model using obese and nonobese data to describe the pharmacokinetics of propofol over a wide range of body weights. A model using allometric scaling of total body weight as the size descriptor of volumes and clearances was better able to characterize propofol pharmacokinetics in obese patients than a model using size descriptors. The same model was later used to control TCI propofol administration in a new cohort of obese patients, and the predictive performance of this model was then compared with that of four other models (Marsh, Schnider, Eleveld, and van Kralingen).[133] While all models tended to underestimate measured concentrations in this study (i.e., measured concentrations were higher than those estimated), the Eleveld model provided the most accurate predictions. When, instead of using the total body weight with the Marsh and Schnider models, an adjusted body weight was used (adjusted weight = ideal weight + 40% × [total – ideal weight]), the predictive performance of these two models were then associated with the lowest MDPE and MDAPE of all models.[133]

Most recently, Cortinez and colleagues used the data from 47 patients enrolled in three previous studies to develop and prospectively evaluate a new pharmacokinetic-pharmacodynamic model for obese patients.[169] Interestingly, during the development phase, allometric scaling did not improve the fit of their new model, and thus their newest model uses linear scaling of compartmental volumes and clearances, with total body weight. When, in the second phase of their study, this newer model was tested prospectively in obese patients, the pharmacokinetic and pharmacodynamic components performed adequately; with regard to the pharmacokinetic component, the predictive performance of the Eleveld model was better than that of their older and newer models, and that of the Schnider model.

Attention has also been focused recently on the performance of propofol models in underweight patients. Lee and colleagues studied the predictive performance of the Marsh and Schnider model in underweight adults and showed that although predictive performance of both models was within limits considered clinically acceptable, the former tended to overestimate plasma concentrations, whereas the Schnider model tended to underestimate plasma concentrations.[135]

Interestingly, when the performance of the older Cortinez model, which uses allometric scaling of total body weight, was studied in volunteers of normal weight, the predictive performance was acceptable and similar to that of the Schnider model.[170] As mentioned earlier, the newer Cortinez model scales volumes and clearances linearly with total weight.[169] It may not extrapolate that well to patients of normal weight, and for this reason the authors do not recommend using it in patients of normal weight.

Different pharmacokinetic-pharmacodynamic models for propofol are associated with different k_{e0} values, which were sometimes derived in very different ways.[12] When effect-site targeting is used, not only is the accuracy of the pharmacokinetic model important for accurate drug administration, the validity of the k_{e0} is also important. First, the value of the k_{e0} will determine the degree of plasma concentration overshoot when the target concentration is increased, and second, it will determine the estimated values of the effect-site concentrations during periods when the plasma and effect-site are not in equilibrium. If one assumes that there is no hysteresis in the relationship between effect-site drug concentration and clinical effect, then it might be rational to evaluate the overall accuracy of propofol pharmacokinetic-pharmacodynamic models by experiments in which propofol is administered by effect-site TCI, by recording a measure of the clinical effect observed over a period of time and then comparing the time course of the estimated effect-site concentrations and clinical effect.

Barakat and colleagues compared the Marsh and Schnider models by observing BIS and MOAA/S scores after starting an effect-site targeted propofol TCI infusion at a fixed target concentration of 2 μg/mL.[171] Subsequently they compared the shapes of the curves of the time course of the estimated effect-site concentration and of measures of clinical effect (BIS and MOAA/S). They found that the shape of the effect-site concentration curve estimated by the Marsh model (with k_{e0} 0.26 min^{-1}) was more similar to the curves for clinical effect than the curve of the effect-site concentration estimated by the Schnider model.[171]

A more objective application of the preceding rationale is to observe clinical effect over a time period when a TCI system estimates that the effect-site concentration is stable. With this approach, one can reason that if the effect-site (target) concentration is kept constant, and there are no other changes (i.e., no other drugs are administered, and no new stimuli), then the most appropriate model will be the one for which a measure of clinical effect is most stable over time.

Using this approach to compare the Schnider and Marsh models, Coppens and coworkers[172] administered propofol by manual infusion until loss of consciousness. They then continued propofol administration in effect-site targeting TCI mode, using as target concentration the estimated effect-site concentration at the moment of loss of consciousness. They found that among 20 patients assigned to effect-site TCI propofol with the Marsh model, BIS values rose and all patients regained consciousness within the subsequent 20 minutes. On the other hand, among the 40 patients assigned to effect-site TCI propofol with the Schnider model (20 with a fixed k_{e0}, and 20 in whom an individual-specific k_{e0} was calculated using the Schnider pharmacokinetic parameters and a fixed time-to-peak effect of 1.6 minutes), only one regained consciousness and there was a general trend for the BIS to decline during the subsequent 20 minutes.

Thomson and colleagues applied the same rationale to a study in which they sought to determine the most suitable k_{e0} for use with the Marsh model when used in effect-site targeting mode for sedation.[173] Six sequential groups received sedation with the Marsh model with the k_{e0} set to 1.2, 0.8, 0.7, 0.6, 0.5, and 0.2 min^{-1}, respectively. In each patient, the initial target concentration was 0.5 μg/mL. Once the effect-site and plasma concentrations were calculated to have equilibrated, the effect-site target concentration was increased in increments of 0.2 μg/mL, until a MOAA/S score of 3 was reached. Thereafter the effect-site target concentration was fixed, and two-choice visual reaction times were recorded. Interestingly, while a k_{e0} of 0.6 min^{-1} seemed best overall, it should be noted that there was considerable interindividual variability. In every group there were patients where the sedation level (just by reaction times) remained stable, whereas in all groups except the 1.2 min^{-1} group there were patients where reaction times decreased (suggesting lightening of sedation depth) and in every group except the 0.2 min^{-1} group there were patients where reaction times increased (suggesting increasing sedation depth).

As mentioned previously, there is no strong consensus on which model is best for propofol administration. Clinician choices concerning which model to use and the mode of use (plasma versus effect-site targeting and method of implementation of effect-site targeting) are largely pragmatically made, based on geographical and historical issues, availability of equipment, and the choices made by the supplier of the equipment.[8,12] More fundamental research is required to better understand the mechanisms of anesthetic-induced loss of consciousness, to determine whether the aforementioned hysteresis occurs, and to subsequently fine-tune our understanding of the pharmacometric principles governing effect-site modeling.[120]

At present a variety of different adult and pediatric models for propofol are used in studies, but also in clinical use, having been implemented in commercially available TCI systems. This generates a potential source of confusion and error. A group in Groningen, The Netherlands, thus combined the data from a large number of pharmacokinetic-pharmacodynamic studies of propofol, involving subjects with a wide range of characteristics (age, weight, and patients vs. volunteers), and used nonlinear mixed effects modeling to generate a single model that applies to all patients. Initially, a pharmacokinetic-only model was produced.[174] This model is able to provide pharmacokinetic parameters for a wide range of patients, from small children to elderly patients, as well as for obese patients. Later a complete pharmacokinetic-pharmacodynamic model was produced, with the pharmacokinetic part involving the same structure as the previous model, but slightly updated parameters, and a sigmoidal Emax pharmacodynamic model.[76] Internal testing of the pharmacokinetic components of both models showed similar or better performance than that of specialist models designed for specific subpopulations (children, elderly, and obese).[76,174]

Model Selection for Target-Controlled Infusion: Pediatric Propofol Models

Two pharmacokinetic models for propofol in children are available in clinical TCI systems. Kataria and colleagues described the time course of propofol plasma concentration in a population of children between ages of 3 and 11 years using a three-compartment model with weight as the sole significant covariate. Weight-adjusting the volumes and clearances significantly improved the accuracy of the pharmacokinetics. Adjusting the pharmacokinetics for inclusion of additional patient covariates or using a mixed-effects model did not further improve the ability of the pharmacokinetic parameters to describe the observations.[175] An alternative propofol TCI model called *Paedfusor*,[153] developed by the Glasgow research group, incorporated a preliminary model published by Schüttler and coworkers[165] and was recently found to be more accurate than the Kataria model. Coppens and associates[31] were the first to publish a combined pharmacokinetic-pharmacodynamic model for propofol in children, revealing a k_{e0} of 0.79 min^{-1} and a Ce_{50} of 3.85 μg/mL as measured using the BIS (Table 26.6). A recent study compared the predictive performance of 11 different models for propofol in children during long-duration anesthesia,[176] and found that in this setting, the Short[177] pediatric model performed best.

As can be seen in Table 26.6, several different models for children are available, and this can lead to errors. This problem, and the potential solution of the Eleveld general purpose model,[76,174] has been discussed previously.

Model Selection for Target-Controlled Infusion: Opioids

Table 26.7 shows the clinically used pharmacokinetic-pharmacodynamic models for remifentanil, fentanyl, sufentanil, and alfentanil. For sufentanil, the covariate model developed by Gepts and colleagues[178] is accurate with MDPE between −2.3% and 22.3% and MDAPE between 18.5% and 29%, even in patients who are obese.[138,148,149] Multiple pharmacokinetic models were developed for alfentanil. A combined analysis of these early study results using a true population analysis was used to develop a new alfentanil model.[179] A comparison showed a better performance for the Maitre alfentanil model (MDPE, 35%; MDAPE, 36%) than the Scott model (MDPE, 12%; MDAPE, 28%).[180] Other studies found contradictory results.[181]

A compartment fentanyl model without covariates specifically aiming for TCI was developed[143] and tested in both lean and obese patients.[144] A simulated plasma concentration required a specific correction in patients who were obese.[144] Various three-compartment combined pharmacokinetic-pharmacodynamic models for remifentanil were developed from studies with both volunteers and patients; however, only the model published by Minto and colleagues is applied in TCI.[61,182] Evaluation of this model showed an acceptable performance, with an MDPE of −15% and an MDAPE of 20%.[150] Because combined pharmacokinetic-pharmacodynamic models are lacking for some of the opioids, the times to peak effect after a bolus administration of alfentanil (1.4 minutes), fentanyl (3.6 minutes), and sufentanil (5.6 minutes) can be applied to calculate the effect-site concentration using the *tpeak algorithm*.[32]

Preliminary remifentanil models in children have been developed. For example, Rigby-Jones and colleagues[183] applied allometric scaling during a study of remifentanil pharmacokinetics in children and reported a single fixed allometric function scaled to a body mass of 10.5 kg that performed well across a broad range of patient weights. More recently, Eleveld and colleagues, using data from a variety of pharmacokinetic-pharmacodynamic studies of remifentanil, involving patients with a wide range of age, height, and weight characteristics, developed a model in which clearances are also allometrically scaled.[184] This model performed well on internal testing and is thought to be suitable for use in all patients, but now requires external prospective validation.

In addition to propofol and the opioids, compartment models have been published describing the time course of the plasma concentration and clinical effect of benzodiazepines, neuromuscular blocking agents, ketamine, and dexmedetomidine, although these drugs have not yet been included in the commercially available TCI pumps.

Rational Target Concentration Selection

No single regimen, concentration, or drug combination applies to all patients. While some sources of interindividual pharmacokinetic and pharmacodynamic variability are known, much of this variability remains unexplained.

Most of the previously mentioned pharmacokinetic-pharmacodynamic models have been derived from population pharmacologic studies. Interpatient variability limits the accuracy of the estimated drug concentration for the individual but can be counteracted if the model is built while exploring a wide variety of possible covariates using parametric modeling, optionally nonlinear mixed-effects modeling. Consequently, caution is needed when applying these models to patients who are obese, older, very young, diabetic, alcoholic, or unwell if similar participants were not part of the study population. The current commercial implementations of TCI, therefore, do not function well when used for patients with characteristics beyond the range of the model's development study population. As illustrated by Absalom and coworkers, the use of specific TCI algorithms outside the original studied population might result in dangerous drug infusion profiles.[12]

These investigators compared two currently used methods for calculating the effect-site concentration for propofol in patients who were obese, one using a fixed k_{e0} and the other using a fixed t_{peak} (see also "Direct-Effect Models" earlier in this chapter).

As the models in clinical use were not developed from data from obese patients, they should not be expected to perform accurately in obese patients. Tachibana and colleagues studied the influence of obesity on the predictive performance of the Marsh model, which scales compartment

volumes linearly with body weight.[134] In their study, they used a single target plasma propofol concentration (4 μg/mL) and found that whereas in nonobese patients the bias was reasonably low, in obese patients measured concentrations were consistently higher than those predicted, to the extent that they found that when they applied a correction factor involving the BMI to the predicted concentration, the bias was reduced.

Growing evidence suggests that gender, ethnic, and racial differences may be important sources of population pharmacokinetic-pharmacodynamic variability and should be considered when designing dosage regimens.[185]

The influence of different factors is often very complex. In one study involving the influence of age and gender on propofol clearance, clearance tended to be higher in females (and it declined with age), whereas age did not appear to have an influence in males.[186] Another study showed that different phases of the menstrual cycle were associated with significant differences in EC_{50} of propofol (predicted concentrations).[187] Xu and coworkers[55] confirmed that race can significantly influence propofol pharmacokinetics and pharmacodynamics. They evaluated the C_{50} for propofol-remifentanil TCI and the BIS at loss of consciousness and the response to noxious stimulus in patients of Chinese ethnicity and revealed that the predicted blood and effect-site concentrations at loss of consciousness were lower than those in previous publications involving Caucasian populations.

An additional caveat is required with the use of different formulations of a drug. For propofol, Calvo and colleagues[188] found that pharmacokinetics and pharmacodynamics were not equal for all formulations, which contributed to an increase in variability of the observed effect. Because of the aforementioned factors, no single regimen, concentration, or drug combination applies to all patients. Some guidance can be found in the ECs at which 50% and 95% of patients have accurate clinical effect (see Table 26.3). As with all drug administration in anesthesia, clinical judgment is always required, and the target concentration should be titrated according to the clinical response of the patient.

One of the major sources of variability in the clinical effect of propofol is interaction with concurrently administered drugs (see prior discussion). The interacting drugs may cause changes in the pharmacokinetics and/or pharmacodynamics of propofol. In this regard, the (mutual) interactions between hypnotics and opioids are currently best understood, but in fact, a wide array of drugs may interact with the hypnotics, including drugs that have been chronically administered during the preoperative phase.[107]

Finally, in individual cases, other obvious sources of reduced single-drug model accuracy are errors such as drug spills, excessive blood loss causing shock, or pharmacokinetic drug interaction.[189-191] The number of factors that can influence drug pharmacokinetics and pharmacodynamics is so large that it would not be practicable to develop models taking all the factors into account, and even less so to have different models to take into account factors such as race. Thus regardless of the accuracy and complexity of available models, it will probably always be necessary for clinicians to titrate anesthetic drug administration to clinical effect.

Benefits of Target-Controlled Infusion

The ability of TCI to rapidly achieve and maintain a steady concentration facilitates attainment of a desired drug effect, irrespective of the absolute achieved drug concentration in the target compartment. The application of TCI in most cases even reduces the variability of intersubject drug-response relationships.[128] As a result, clinical outcomes when comparing TCI versus manual infusion were found to be improved in various early studies, although contradictions exist in the literature.

In the 1980s, Ausems and coworkers[192] compared pharmacokinetic model–driven administration with intermittent bolus administration of alfentanil. Automated drug delivery produced fewer episodes of muscular rigidity, hypotension, and bradycardia on induction. Automated drug delivery during maintenance resulted in a significantly less frequent incidence of hemodynamic response, which resulted in a larger percentage of anesthesia time within

15% of the desired arterial blood pressure and heart rate. Recovery after TCI was associated with significantly less use of naloxone for adequate ventilation. Pharmacokinetic model–driven infusion of fentanyl during cardiac surgery resulted in better hemodynamic control with fewer additional drug interventions and significantly fewer episodes of either hypotension or hypertension than with bolus dose administration.[193]

Theil and colleagues[194] compared double-blind manual administration of fentanyl-midazolam with pharmacokinetic model–driven infusion of these two drugs in a small group of patients undergoing cardiac surgery. Both systems were simultaneously titrated (one containing placebo), with the aim of maintaining hemodynamics within 20% of baseline values. Both systems were equally effective in providing hemodynamic control as dictated by the protocol. The most significant difference between the two modes of delivery was the greater variability in drug plasma concentrations in the manual group, which suggested that pharmacokinetic model–driven infusion maintained patients within a more narrow therapeutic range.

TCI remifentanil provides improved hemodynamic control both intraoperatively and postoperatively with less remifentanil and similar propofol infusion rates.[195] Age dramatically influences the pharmacokinetics of remifentanil; consequently, a TCI model that includes age will result in a beneficial drug titration compared with a standard µg/kg/min infusion. For deep sedation in spontaneously breathing patients, Moerman and associates[196] found that the combination of remifentanil and propofol offered better conditions for colonoscopy than propofol alone; and that TCI remifentanil administration was associated with reduced propofol dosing and a less frequent incidence of apnea and respiratory depression, compared with manually controlled administration. Others have confirmed this finding.[192]

Using the first commercially available TCI system (Diprifusor), early studies administering propofol by plasma-targeted TCI showed some benefits.[159,197,198] These revealed a significant preference of clinicians for the TCI system, although this was their first use of the device.

Passot and coworkers[199] compared TCI and manual propofol infusion in high-risk older patients undergoing hip fracture surgery and concluded that TCI improved the time course of propofol-induced hemodynamic effects in these patients. Chen and colleagues found that similar induction and total doses of propofol were used when anesthesia was induced and maintained with either a manual or a TCI system, and the propofol administration was titrated to achieve a specific BIS value.[200]

Wang and colleagues compared the clinical conditions associated with TCI and manual propofol infusion during asleep-awake-asleep epilepsy surgery. TCI was associated with significantly improved awakening times and higher BIS values after the first asleep phase.[201] Chiang and associates found similar results when they compared TCI with manually controlled propofol infusions for combined upper and lower endoscopy.[202] Patients in the TCI group had better hemodynamic and respiratory stability and recovered more quickly from sedation than patients assigned to the manually controlled infusion group.

The Irwin group recently compared TCI and manual propofol administration in children.[203] Although they found that in children assigned to TCI propofol administration, higher total propofol doses were given, the amount of time the BIS was in an optimal range was greater and recovery times were similar. The authors concluded that TCI might facilitate easier titration of propofol to clinical effect.

TCI can theoretically facilitate rational drug administration for patients in the ICU, where drugs are commonly administered for prolonged periods. In this situation, by taking account of drug redistribution and eventually equilibration between compartments and thus reducing infusion rates, TCI systems have the potential to assist with maintenance of more stable sedation levels. McMurray and coworkers[156] studied TCI propofol in 122 adult ICU patients. Bias and median absolute performance error were within acceptable ranges at 4.3% and 19.6%, respectively. Acceptable sedation levels occurred for 84% of the sedation period. They proposed propofol plasma targets between 0.2 and 2.0 µg/mL for ICU sedation.

Overall, there is little high-quality evidence of improved outcome with the use of TCI as opposed to manual drug administration. Nonetheless, the popularity of TCI use has grown significantly since the introduction of the first commercially available devices. The systems are registered for use in at least 93 countries of the world, and we recently estimated that in Europe alone, more than 2 million patients per year received one or more drugs administered with a TCI system.[8]

Plasma Versus Effect-Site Targeting

Using experimental systems, Glass[123] and Struys[47] and their colleagues conducted similar studies in which they targeted either plasma or effect-site concentration of propofol and then observed the time and plasma versus effect-site concentration at loss of consciousness. In both studies, regardless of whether the effect-site or plasma concentration was targeted, loss of consciousness occurred when the appropriate *effect-site* concentration for loss of consciousness was achieved, thus validating the concept. Two other important observations were made during these studies. First, hemodynamic stability was not different for plasma or the effect-site targeting, although higher plasma concentrations were achieved in the effect-site group. This finding implies, at least for propofol, that the time course for its hemodynamic effects is similar or longer[204] to that for its anesthetic effects. Second, k_{e0} is dependent on the pharmacokinetic set from which it is derived.[32] A k_{e0} value cannot be taken from one pharmacokinetic set and used with another pharmacokinetic set.[31] Just as various demographics may alter the pharmacokinetics, they may also alter k_{e0}. Therefore using the k_{e0} best adapted for the clinical milieu is desirable. An ideal test of whether targeting plasma or the effect site is better is to compare their use in a closed-loop system in which a measure of effect (e.g., the BIS) is used as the target of control. In a small study of 10 patients per group, Absalom and Kenny showed that maintenance of the targeted BIS (as measured by MDPE, MDAPE, and wobble) was somewhat improved and induction times were significantly shorter when the pharmacokinetic model was for the effect site rather than for the plasma.[205] Effect compartment–controlled TCI systems are currently commercially available in many countries (not the United States).[8] They may offer better control of the dose-response relationship.[47,206,207]

Safety of Target-Controlled Infusion

In noncomparative studies, pharmacokinetic model–driven infusion has been used to administer most of the potent opioids, as well as the hypnotics. Different anesthetic techniques have also been tested with pharmacokinetic model–driven infusion devices, including nitrous oxide–opioid anesthesia, supplementation of volatile anesthetics, total intravenous anesthesia, sedation for monitored anesthesia care, and ICU sedation. In all these studies, outcome as measured by hemodynamics and recovery has been within the expectations of normal clinical care. Etomidate, methohexital, midazolam, propofol, thiopental, dexmedetomidine, alfentanil, fentanyl, remifentanil, and sufentanil have all been used with TCI. When these drugs were used with target-controlled drug delivery systems for total intravenous anesthesia or to supplement nitrous oxide or volatile anesthetics, hemodynamics were well maintained during induction and intubation, as well as during maintenance. Recovery milestones were reached at times comparable with those achieved with similar drug combinations used in manual infusion schemes. None of these studies have reported adverse outcomes resulting from target-controlled drug delivery.

A recent review shows that the safety and reliability of commercially available TCI systems has been exemplary, suggesting that the systems perform as intended and programmed.[127] Despite use of TCI systems in millions of patients around the world, a search of the medical literature, regulatory reports, and company safety statements revealed only a handful of possible problems specific to TCI device use, many of which were the result of user error and none of which resulted in product recalls or patient harm.

PATIENT-CONTROLLED ANALGESIA AND SEDATION

A particular method of intravenous drug administration is patient-controlled analgesia, mostly used for the postoperative administration of analgesics or for patient-controlled sedation (PCS) during therapeutic procedures. Although PCA can be considered as a method of computer-controlled or even closed-loop drug administration, most of these pumps currently do not include pharmacokinetic or pharmacodynamic algorithms. In some cases, the PCA or PCS pump is set to deliver a low, constant or *background* flow of medication. Additional doses of medication can be self-administered by the patient pressing a button as needed. Most commonly, no background infusion is provided, and the patient controls when he or she receives an analgesic bolus. To avoid overdosing, these pumps have built-in safety mechanisms such as lock-out times and limitations of the total amount of drug delivered per time unit. PCA is a common technique for delivery of postoperative pain medication such as morphine, piritramide, fentanyl, tramadol, and other drugs.[208-212] In a systematic review, Walder and colleagues showed that the literature presented some evidence that in the postoperative pain setting, PCA with opioids, compared with conventional opioid treatment, improved analgesia and decreased the risk of pulmonary complications; in general, patients preferred the technique.[213] Strict hospital guidelines may help avoid side effects such as oversedation and respiratory depression.[214] When epidural analgesia is contraindicated during labor, remifentanil PCA has been suggested as an alternative. Pilot trials suggested that this alternative is safe under strict observation.[215-220] However, a more recently published randomized-controlled trial showed that, in comparison with epidural analgesia, not only was remifentanil PCA associated with lower satisfaction scores, it was also associated with lower maternal oxygen saturation values.[221]

Although popular, PCA systems are imperfect, as they administer boluses that result in a time course of clinical effect that is unlikely to accurately match the time course of the painful stimulus the patient is suffering. The same applies to PCS systems, except that here the bolus will provide a time course of sedation or anxiolysis that does not match the experience of the patient. TCI technology has thus also been applied to PCA and PCS. With these patient-maintained analgesia and patient-maintained sedation systems, the system administers a TCI of analgesic or sedative, usually starting at a fixed low-target concentration, and after an initial period the patient is able to influence the target concentration. In some initial studies the target concentration was increased or decreased by a researcher using an algorithm,[70,74,180,211,222,223] but in others the patient was able to activate target concentration increases by pressing the button of a handset, once a lockout period had passed.[224]

Van den Nieuwenhuyzen and colleagues demonstrated the advantages of PCA-TCI with alfentanil over routine morphine PCA for postoperative analgesia.[74,180,222,223] Analgesia support using effect-site targeted TCI of remifentanil or fentanyl during extracorporeal shock-wave lithotripsy was tested by Cortinez and colleagues.[70] They found a remifentanil and fentanyl EC_{50} of 2.8 ng/mL and 2.9 ng/mL. At EC_{50}, the probability of having a respiratory rate less than 10 was 4% for remifentanil and 56% for fentanyl. Hypoxemia, vomiting, and sedation were more frequent in the fentanyl group, making this drug less suitable for this clinical application than remifentanil. Lipszyc and associates[211] used remifentanil effect-site PCA-TCI with a slow and progressive adapted algorithm for treatment of acute pain after uterine artery embolization and showed that it provided better care than PCA morphine in the first 4 hours of administration.

Schraag and colleagues studied the efficacy and safety of a remifentanil patient-maintained analgesic system for early analgesia after orthopedic surgery.[224] If the patient operated an activating handset then the target concentration was increased by 0.2 ng/mL; otherwise the system gradually reduced the target. The system was found to provide satisfactory analgesia, with little sedation and few respiratory adverse effects.

Jeleazcov and colleagues have developed and studied a TCI-PCA system for hydromorphone.[225] With this system the patient is also able to request higher target concentrations by means of a button push. The authors found that patients using this system after cardiac surgery had satisfactory pain control with only moderate adverse effects.

The initial developments of PCS systems enabled the patient to request bolus drug administration (propofol or midazolam), or occasionally an increase in drug infusion rate.[226-230] Studies on the quality and outcomes after PCS have shown that it reduces discomfort and fear by inducing sedation and amnesia during uncomfortable therapeutic procedures such as colonoscopy. Additionally, PCS facilitates the procedure by increasing the patient's tolerance. Although propofol offers no analgesic effect, several studies of patient control of propofol administration (bolus or short infusions) during procedures showed that it provided reasonably safe, light sedation, and that patients expressed a preference for being in control.[227,229,230] A recent study compared physician-controlled TCI propofol with PCS with boluses of propofol during endoscopic retrograde cholangiopancreatography. It showed that with PCS lower doses of propofol were used and recovery was more rapid.[231]

As bolus or even manual infusion regimens might produce fluctuating levels of sedation, Kenny and colleagues in Glasgow combined PCS with TCI of propofol to overcome this problem. Using a patient-maintained sedation system, the patient can set a specific propofol target concentration using an activating handset button. With the system, the patient was required to press twice within one second to request a target increase. If no validated presses occurred, the system initially kept the target propofol concentration unchanged, but if after 6 minutes no further presses occurred, then the target concentration was reduced by the incremental amount. A starting concentration and a lockout time is set by the clinician (commonly with the default being approximately the equilibration time between plasma and effect-site concentrations). In various applications requiring sedation, their experimental system was shown to be feasible[232-235]; however, even when using an effect-site controlled TCI system, some volunteers rendered themselves unconscious.[236] Whereas the system developed by Kenny and colleagues incorporated the Marsh model, Stonell and colleagues developed and tested a system enabling propofol effect-site targeted patient-maintained sedation with the Schnider model. They compared patient-maintained sedation with anesthetist-administered sedation and found that patient-maintained sedation was associated with fewer adverse events, higher sedation scores, and BIS values, but at the cost of slower induction times, while patient and operator satisfaction was similar.[237]

It is possible that safety can be improved further, particularly if a test or measure of responsiveness to a stimulus is added and if the control algorithm is incorporated to allow the facility to stop the infusion should the response become inadequate.[238-241]

Doufas and colleagues tested an automatic response test to optimize propofol administration for conscious sedation.[242,243] Although volunteers were required to push a delivery button in response to auditory and tactile stimuli, a TCI-like algorithm guided the propofol administration. The study showed that failure to respond to automated responsiveness monitoring precedes potentially serious adverse effects of sedation such as loss of responsiveness, and that the monitor was not susceptible to false-positive responses.[244]

An enlarged commercial version of this device, SEDASYS (Ethicon Endo-Surgery, Cincinnati, Ohio), was tested in two studies. It incorporated the automated responsiveness monitoring and built-in capnography and pulse oximetry. If the patient's responses to stimuli were inadequate, then the subsequent increases in infusion rates were limited. If apnea or hemoglobin oxygen desaturation were detected, then the infusion was stopped and additional oxygen given. After a successful feasibility study,[245] the system was then used in a large randomized study of sedation during upper gastrointestinal endoscopy and colonoscopy and was found to be associated with a reduced incidence of adverse events compared with standard care (5.8% vs. 8.7%, respectively).[246] Although the device was approved by the FDA in 2013 for the provision of moderate sedation during routine endoscopic procedures in ASA 1 and 2 patients, poor sales figures prompted a commercial decision by the vendor to cease marketing the device.[247,248]

Closed-Loop Controlled Intravenous Drug Delivery

The next step in computer-controlled drug delivery is to feed a continuous measure of drug effect directly back to the automated drug delivery device, thus providing a continuous closed-loop system. This system avoids the requirement of a clinician to titrate the target concentration manually, based on intermittent observations of the desired therapeutic effect. With manual control, attempts to achieve tight titration of hypnosis require high clinical expertise and a labor-intensive process and may divert the clinician's attention from critical actions resulting in a suboptimal therapy or even threatening the patient's safety. Applying closed-loop drug administration techniques could optimize this process of dose titration.[4] The application of closed-loop systems for drug administration is complex and requires a perfect balance for all the basic components of such a system: (1) a control variable representative for the targeted therapeutic effect; (2) a clinically relevant set-point or target value for this variable; (3) a control actuator which is, in this case, the infusion pump driving the drug; (4) a system, in this case a patient; and (5) an accurate, stable control algorithm.[249]

Control algorithms are all based on measuring the error between the target and the observed effect. Various control strategies are described in the literature to steer this closed-loop administration. Proportional-integral differential (PID) controllers are frequently used in engineering applications. This controller will adjust the infusion rates in a manner that is proportional to the magnitude of the error, the integral of the error over time, and the derivative of the error over time. The fine-tuning of a PID controller might be difficult in this particular setting because of the complexity of the system to control and the interindividual pharmacologic variability, and because directly counteracting the administration of excessive drug is not possible. A more appropriate approach could be to use a PID control system connected to a TCI system to decrease the order of complexity between dose and response (see Fig. 26.26).[250] An alternative control strategy is called *model-based adaptive control*. This controller has an internal model of the system, typically set up as an integrated pharmacokinetic-pharmacodynamic model that relates dose to concentration (pharmacokinetics) and concentration to drug effect (pharmacodynamics). The model is updated to explain the difference between the measured and predicted drug effect.

A reliable physiologic signal, which is a measure of the clinical drug effect, is the most important component of closed-loop technology. Vital signs such as arterial blood pressure or muscle activity have been used to guide intravenous closed-loop drug administration. For example, Kenny and coworkers[251] successfully evaluated closed-loop control of arterial blood pressure using a mixture of trimethaphan camsylate and sodium nitroprusside during controlled hypotensive anesthesia for local resection of intraocular melanoma. In the 1980s and the 1990s, various researchers investigated the accuracy of closed-loop controlled administration of atracurium[252,253] and vecuronium.[254] However, since the introduction of the novel reversal drug, sugammadex, interest in closed-loop administration of vecuronium or rocuronium has significantly declined.

The commercialization of various EEG-based *depth of anesthesia* monitors, such as the BIS, spectral entropy, and auditory-evoked potential, has renewed the interest of various research groups in closed-loop administration of intravenous hypnotics. Using an early version of the BIS as the control variable, Sakai and colleagues[255] concluded that their closed-loop system provided intraoperative hemodynamic stability and a prompt recovery from sedative-hypnotic effects of propofol. A similar propofol closed-loop system using the BIS and PID control of a plasma-controlled TCI system showed acceptable control during major orthopedic surgery[256] and during sedation.[257] Although these investigators improved the performance of their control system by switching toward effect-site targeted TCI, they also concluded that the PID controller might still face some stability problems. Similarly, Liu and colleagues used a closed-loop titration of TCI based on a proportional-differential algorithm guided by the BIS, allowing induction and maintenance of general anesthesia and compared this with manual propofol TCI. They found that closed-loop control resulted in less propofol consumption and longer induction times but with better hemodynamic stability, less excessive anesthetic levels (BIS <40), similar hemodynamic stability, and faster recovery.[250,258]

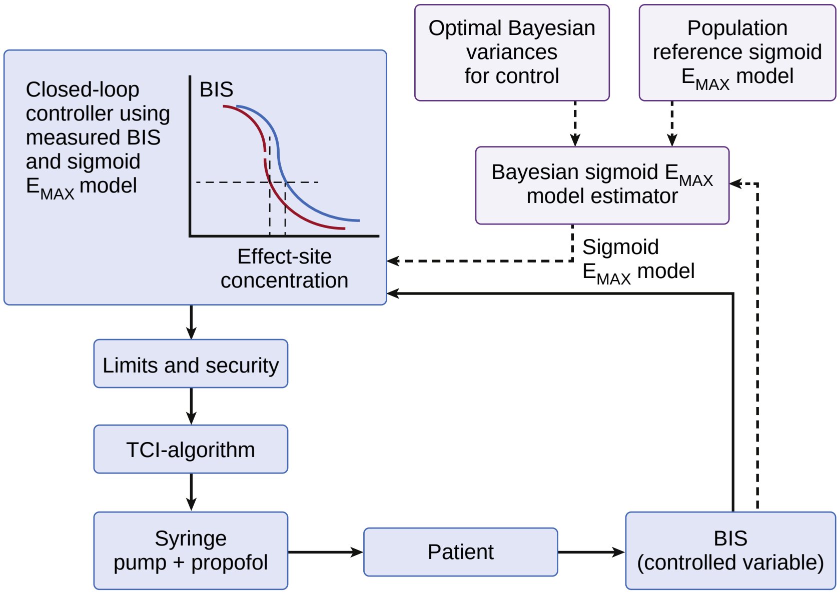
Liu and colleagues have developed a more advanced version of their initial system, now using full PID control, for closed-loop coadministration of both propofol and remifentanil, using the BIS as the controlled variable. A rule-based algorithm decides when to change the propofol or remifentanil targets. In a multicenter study, this system showed a better overall performance versus manual administration.[259] A similar approach was used with an alternative EEG-derived index, spectral entropy.[260] The same group has since used their system in various groups of patients in a variety of clinical settings, such as during sedation, pediatric surgery, and liver transplantation—and in a variety of applications in which it is used to provide an objective evaluation of the influence of pharmacological (e.g., use of dexmedetomidine) and nonpharmacological interventions (e.g., hypnosis) on anesthetic drug requirements for general anesthesia.[261-269]

Puri and colleagues in India developed a system that incorporates an adaptive PID algorithm to control propofol administration guided by the BIS. It has been extensively tested in a variety of circumstances, for general anesthesia and postoperative sedation, in adults and children, at high altitude, and in patients with pheochromocytoma and heart failure, and found to perform satisfactorily.[270-276] In a randomized controlled trial involving more than 200 patients, the system was shown to provide significantly more accurate control (defined as BIS within target range) than manually controlled anesthesia.[277]

A Canadian group lead by Dumont and Ansermino have also developed a PID-based closed-loop controller. For their system, they developed their own monitor (NeuroSENSE, NeuroWave Systems, Cleveland Heights, OH), which calculates the wavelet-based anesthetic value for central nervous system monitoring (WAV_{CNS}) and the burst suppression ratio.[278,279] The WAV_{CNS}, which has a range of 0 to 100, has also been used for monitoring sedation in the ICU.[280] A study comparing the performance of WAV_{CNS} with BIS and response entropy found that WAV_{CNS} performed well, and was particularly good at capturing rapidly occurring changes.[281] The system includes a PID algorithm, and initially was only used to control a propofol infusion.[282] It contains an infusion safety system to manage the infusion rate when the feedback variable (WAV_{CNS}) is unavailable or when the drug infusion exceeds predefined limits. Later, they developed and tested a so-called multi-input single-output system, in which the output remained the WAV_{CNS}, but the controller was able to control both a propofol and a remifentanil infusion.[282] The authors have shown that their system provides robust, stable, and safe control of anesthetic depth, even under challenging conditions such as significant bleeding,[283] and that the addition of automatic control of remifentanil administration improved the quality of control.[282]

Another group in Canada have gradually taken their closed-loop system (McSleepy) to the next level. Their initial version of McSleepy used a PID algorithm and the BIS to automatically control a propofol infusion and was shown to be able to provide more accurate and stable control of the BIS than an anesthesiologist manually controlling the propofol infusion rate.[284] They then developed McSleepy further to enable closed-loop control of three drugs: propofol and remifentanil infusions, and rocuronium boluses.[285] For propofol, a proportional integral algorithm is used with the BIS the control variable, whereas for remifentanil a rule-based proportional algorithm is used to control the Analgoscore (a nociception score based on heart rate and blood pressure),[286] and finally, rocuronium boluses are administered on the basis of simple rule set, to keep the train of four count less than 25%. This system has been shown to provide accurate control of all variables. The system has been adapted (the Analgoscore was adapted and the name changed to NociMap) and used for general anesthesia for cardiac surgery,[287] and more recently also adapted to provide propofol sedation[288] and used during transcatheter aortic valve implantation.[289]

Model-based adaptive control of BIS-guided propofol administration was previously used by Struys and colleagues for sedation during spinal anesthesia and for general anesthesia.[290,291] The control algorithm is based on a patient-specific pharmacodynamic profile estimated during induction. Compared with manually titrated propofol administration, patients in the closed-loop group reached the target BIS at a somewhat slower rate, but this resulted in less BIS overshoot and better hemodynamics after induction. During the maintenance phase, improved control of the BIS and systolic blood pressure was found in the closed-loop group and recovery was faster. Using simulations, these authors compared their model-based control system with a previously published PID controller



Optimal Bayesian variances for control

Syringe pump + propofol
Patient
BIS (controlled variable)

Fig. 26.32 Flow chart of the closed-loop system. The *solid lines* represent the closed-loop control system. Each time the required effect-site concentration is calculated by the controller this value is sent to an additional algorithm, taking the safety limits into account. The result of these calculations is the required effect-site concentration sent to the target-controlled infusion *(TCI)* algorithm, which steers a pump injecting propofol to the patient. The measured bispectral index *(BIS)* is used as the input of the closed-loop controller. The *dotted lines* represent the Bayesian sigmoid E_{MAX} model estimator. The estimator receives a priori information from the population sigmoid E_{MAX} model, the optimal Bayesian variances for control, and the patient-measured BIS values. (From De Smet T, Struys MM, Greenwald S, et al. Estimation of optimal modeling weights for a Bayesian-based closed-loop system for propofol administration using the bispectral index as a controlled variable: a simulation study. *Anesth Analg.* 2007;105:1629–1638. Used with permission.)

and found that the model-based controller outperformed, even under extreme control conditions such as low and high BIS levels and abrupt changes in the BIS levels.[292] De Smet and Struys later developed the adaptive part of the controller using Bayesian optimization (Fig. 26.32)[293] and compared the feasibility and accuracy of this system with manually controlled BIS-guided, effect compartment–controlled propofol TCI during ambulatory gynecologic procedures. They found that the closed-loop control system accurately titrated propofol administration resulting in BIS values close to the set point. The closed-loop control system was able to induce anesthesia in the patients within clinically accepted time limits and with less overshoot than the manual control group. Automated control resulted in beneficial recovery times. This closed-loop control group showed related acceptable clinical performance specified by similar hemodynamic respiratory stability, comparable movement rates, and quality scores as the manual control group.[294]

Alternative closed-loop systems have been developed for isoflurane administration using a controller with a cascade structure, originally described by Gentilini and associates.[295,296] More recently, Moore and Doufas designed a closed-loop system using an intelligent system technique called *reinforcement learning*, known as a mathematically robust method of achieving optimal control in systems challenged with noise, nonlinearity, time delay, and uncertainty.[297,298]

So far, closed-loop systems have only been used under strict experimental conditions. The challenge is now to prove their safety and utility when applied in clinical practice.[299,300] Liu and associates have shown improved stability of control of depth of anesthesia with their system in a large multicenter study.[259] More recently two meta-analyses have evaluated the available data concerning the performance of closed-loop systems for intravenous anesthesia and other applications.[301,302] Both found improved accuracy of control with closed-loop technology.

Liu and associates have also been able to show that the use of their system produces several secondary benefits, such as a reduction in the workload of the anesthesiologist.[303] Ultimately, clinicians will have to determine whether adaptive, intelligent computer systems with dual, interacting, closed-loop systems will facilitate better control and improve patient outcomes.[120]

Although closed-loop technology and automation are almost ubiquitous in our daily lives, closed-loop anesthesia is still only used within research settings. Recent editorials have discussed the relevance of closed-loop technology to anesthesia, and the likely time course over which applications will become a routine part of our daily work.[304-306] The theoretical benefits, however, are compelling, and so it is not surprising that the FDA recently held a workshop on the regulatory considerations for physiological closed-loop controlled medical for automation in critical care and anesthetic environments, and is currently formulating recommendations and regulatory proposals.[307]

Future Perspectives

For all existing drugs there is broad pharmacokinetic and pharmacodynamic variability. In anesthesia practice, inaccurate dosing can have serious consequences. Whereas overdosing might be associated with hemodynamic compromise and prolonged recovery, underdosing is particularly undesirable since it can result in unintended awareness during general anesthesia, with severe psychological consequences.[308] A recent study involving all hospitals in the United Kingdom and Ireland showed that accidental awareness during general anesthesia was more common with intravenous anesthesia compared with inhalational anesthesia.[309] Thus for intravenous drug delivery, there remains a strong need for methods to ensure accurate and individualized estimation and titration of dosing. Currently there exist several emerging techniques and technologies that might help realize this goal.

Hypnotic drugs used in anesthesia are known to have strong interaction reactions with other commonly used drugs. While pharmacokinetic interactions are common, pharmacodynamic interactions are much larger in magnitude, and thus clinically highly relevant. In the case of the hypnotics and opioid analgesics, the interactions are strongly synergistic, and so when these drugs are coadministered, dose adjustments are usually necessary to avoid adverse effects. These interactions are very complex, with the magnitude of the interaction effect dependent on the plasma and effect-site concentrations of all of the interacting drugs. Interactions between two drugs are best depicted on three-dimensional response surface plots.[80,96,99] As mentioned earlier, advisory displays have been developed to provide the anesthesiologist with real-time information on the likely magnitude of the clinical effect of drug combinations (see Fig. 26.25). Although seldom used in clinical practice, it is likely that these and similar systems will be more widely employed in the future, to help guide anesthesiologists to optimize anesthetic dosing.

A development that could potentially improve safety and accuracy is the broader implementation and clinical use of the new “universal” pharmacokinetic-pharmacodynamic models that have been developed for propofol[76] and remifentanil.[184] The models currently used to implement TCI were developed from studies of patients or volunteers with a rather narrow range of age, weight, and height characteristics; and so naturally these models are only applicable in patients of similar characteristics. On the other hand, the universal models were developed from a combined analysis of the data from a significant number of studies involving a large number of patients with different characteristics. The origin of the underlying data, along with the use of allometric scaling, should broaden the applicability of these models. Once these models have been prospectively validated, it is hoped that availability of a single, accurate model for propofol and remifentanil will enhance patient safety and encourage infusion system manufacturers to incorporate these models into their TCI pumps. This might also help reduce the likelihood of drug errors (e.g., those resulting from choice of an inappropriate model, or a lack of understanding of the model chosen), and this too might help improve the popularity and broaden the applications of TCI systems.

TCI systems contain population pharmacokinetic models, designed to provide the best estimate of the parameters of drug kinetics in a population, but not necessarily for an individual. Inevitably, there will be some degree of error when a pharmacokinetic-pharmacodynamic model is used to guide or determine drug infusion rates to a single patient. One possible solution to the inevitable problem of any mismatch between the pharmacokinetic behavior of a drug and the pharmacokinetic model used to guide administration is to perform real-time measurements of achieved concentrations, and to individualize the model. Recently, a system has become available that provides accurate point-of-care measurement of plasma propofol concentrations within 5 minutes.[310] Plasma propofol concentrations measured by this apparatus were thus used in a system that used Bayesian methodology to update the pharmacokinetic-pharmacodynamic model being used for TCI administration of propofol.[136] Although the results were somewhat disappointing—after adaptation bias improved, but precision did not—this was an initial effort using this system, and future research developments might show better results.

At present, no real-time plasma concentration measurements of intravenous drugs are routinely available for clinical use. Such measurements may improve drug delivery or might optimize TCI administration for the individual patient.[311] Several promising techniques have been described. Takita and colleagues found a strong and linear correlation between exhaled propofol concentrations measured by proton transfer mass spectrometry and estimated and measured arterial propofol concentrations.[312] Miekisch and coworkers[313] used headspace solid-phase microextraction coupled with gas chromatography mass spectrometry to measure alveolar (exhaled), arterial, central venous, and peripheral blood propofol concentrations, and found a good correlation between exhaled and arterial concentrations. Perl and colleagues[314] used an ion mobility spectrometer coupled to a multicapillary column for preseparation (multicapillary column–ion mobility spectrometer [MCC-IMS]), Hornuss and colleagues used ion molecule reaction mass spectrometry,[315,316] and Grossherr and colleagues used gas chromatography mass spectrometry.[317] The latter group also described the difference between blood/gas partition coefficient and pulmonary extraction ratio for propofol between species, which will be important when studying this technique in an animal setting.[318]

Varadajan,[319] Ziaian and colleagues,[320] and Kreuer and colleagues[321] have applied compartmental modeling to describe the kinetics of exhaled propofol. Colin et al. were able to show that standard compartmental models can easily be extended with an additional lung compartment (with a rate constant to model time delay) and a scaling factor (to convert units) to enable predictions of plasma propofol concentration, as well as online Bayesian model adaptation.[322] With this model it was also possible to estimate BIS values from exhaled propofol measurements.

Recently a system using MCC-IMS (Edmon, B. Braun, Germany) has become commercially available and is able to provide measurements every minute. Studies with a prototype system used a reference gas generator to confirm accuracy and precision over the clinical range of exhaled propofol measurements.[323]

Even with an online method for measurement of drug concentrations and/or of perfecting pharmacokinetic models, the clinician still faces the challenge of the broad variability in pharmacodynamic response to any given drug concentration. Automatic closed-loop control systems, which have been discussed extensively in this chapter, might provide a solution to this problem. A well-designed system with a robust measure of clinical effect should help to optimize drug administration and titration on an individual level by accurately titrating drug administration to clinical effect.

Finally, the use of nonlinear mixed effects modeling (NONMEM) techniques is currently considered to be the state-of-the-art for pharmacokinetic-pharmacodynamic analysis and for development of new models. Such development involves use of infusion rate, measured plasma concentration, and measures of clinical effect to generate mathematical models that are consistent with our knowledge of pharmacology.

This process produces the parameters for a structural model comprising two or more compartments, redistribution clearance, and metabolic clearance parameters that describe exponential processes. Artificial intelligence approaches using neural networks are providing powerful and effective solutions to modern problems, eliminating the need to start with models based on current knowledge.[324] This "deep learning" approach was recently applied to data from 231 patients to learn how to predict the BIS values associated with differing plasma and effect-site concentrations of propofol and remifentanil.[325] Remarkably the system was able to learn to predict BIS values more accurately than traditional pharmacokinetic-pharmacodynamic model-based approaches. Given the widespread ease of access of almost all anesthesiologists to web-based technology, it is reasonable to imagine a situation where the data from millions of patients around the world are fed into machine-learning systems that can learn to predict responses to different combinations of drugs, and, inversely, learn to accurately predict the doses required for given responses, without the need for complex models.

Pharmacology of Neuromuscular Blocking Drugs

SORIN J. BRULL and CLAUDE MEISTELMAN

KEY POINTS

- Two different populations of nicotinic acetylcholine receptors exist at the mammalian neuromuscular junction. In the adult, the nicotinic acetylcholine receptor at the postsynaptic (muscular) membrane is composed of $\alpha_2\beta\delta\varepsilon$ subunits, while the fetal (immature) receptor is composed of $\alpha_2\beta\gamma\delta$. The presynaptic (neuronal) nicotinic receptor is a pentameric complex composed of $\alpha_3\beta_2$ subunits. Each of the two α subunits of the postsynaptic receptors has a ligand (acetylcholine) binding site.
- Nondepolarizing muscle relaxants produce neuromuscular blockade by competing with acetylcholine for the postsynaptic α subunits. In contrast, succinylcholine acts directly with the recognition sites and produces prolonged depolarization that results in decreased sensitivity of the postsynaptic nicotinic acetylcholine receptor and inactivation of sodium channels so that propagation of the action potential across the muscle membrane is inhibited.
- Different patterns of stimulation examine neuromuscular blockade at different areas of the motor end plate. Depression of the response to single twitch stimulation is likely caused by blockade of postsynaptic nicotinic acetylcholine receptors, whereas fade in the response to tetanic and train-of-four stimuli results from blockade of presynaptic nicotinic receptors.
- Succinylcholine is the only available depolarizing neuromuscular blocking drug for clinical use. It is characterized by rapid onset of effect and ultrashort duration of action because of its rapid hydrolysis by butyrylcholinesterase.
- Available nondepolarizing neuromuscular blocking drugs can be classified according to chemical class (aminosteroid, benzylisoquinolinium, or other compounds) or by duration of action (long-, intermediate-, and short-acting drugs) of equipotent doses.
- The speed of onset is inversely proportional to the potency of nondepolarizing neuromuscular blocking drugs. With the exception of atracurium, molar potency is highly predictive of a drug's rate of onset of effect. Rocuronium has a molar potency that is approximately 13% that of vecuronium and 9% that of cisatracurium. Its onset of effect is more rapid than either of these muscle relaxants.
- Neuromuscular blockade develops faster, lasts a shorter time, and recovers faster in the more centrally located neuromuscular units (e.g., laryngeal adductors, diaphragm, and masseter muscle) than in the more peripherally located adductor pollicis muscle.
- Many long-acting neuromuscular blocking drugs undergo minimal or no metabolism, and they are primarily eliminated, largely unchanged, by renal excretion. Neuromuscular blocking drugs of intermediate duration of action have faster distribution and more rapid clearances than the long-acting drugs because of multiple pathways of degradation, metabolism, and elimination. Mivacurium, a short-acting neuromuscular blocking drug, is cleared rapidly and almost exclusively by metabolism by butyrylcholinesterase.
- After the administration of nondepolarizing neuromuscular blocking drugs, it is essential to ensure adequate return of normal neuromuscular function using objective (quantitative) means of monitoring. Residual neuromuscular paralysis decreases upper esophageal tone, coordination of the esophageal musculature during swallowing, and hypoxic ventilatory drive. Residual paralysis can increase healthcare costs and the patient hospital length of stay, morbidity, and mortality.

History and Clinical Use

In 1942, Griffith and Johnson described *d*-tubocurarine (dTc) as a safe drug to provide skeletal muscle relaxation during surgery.[1] One year later, Cullen described the use of this drug in 131 patients who had received general anesthesia for surgery.[2] In 1954, Beecher and Todd reported a six-fold increase in mortality in patients receiving dTc compared with patients who had not received a muscle relaxant.[3] The increased mortality resulted from a general lack of understanding of the clinical pharmacology and effects of neuromuscular blocking drugs (NMBDs). The effect of residual neuromuscular blockade postoperatively was not appreciated, guidelines for monitoring muscle strength had not been established, and the importance of pharmacologically antagonizing residual blockade was not understood.

Succinylcholine, introduced by Thesleff[4] and Foldes and associates[5] in 1952, rapidly gained widespread use and changed anesthetic practice drastically because the drug's rapid onset of effect and ultrashort duration of action allowed for both rapid endotracheal intubation and rapid recovery of neuromuscular strength.

In 1967, Baird and Reid reported on the clinical administration of the first synthetic aminosteroid, pancuronium.[6] The development of the intermediate-acting NMBDs was based on the compounds' metabolism and resulted in the introduction of vecuronium,[7] an aminosteroid, and atracurium,[8] a benzylisoquinolinium, into clinical practice in the 1980s. Vecuronium was the first muscle relaxant to have an intermediate duration of action and minimal cardiovascular actions. Mivacurium, the first short-acting nondepolarizing NMBD, was introduced into clinical practice in the 1990s,[9] as was rocuronium,[10] an intermediate-acting NMBD with a very rapid onset of neuromuscular blockade. Other NMBDs have been introduced into clinical practice since the use of dTc was first advocated. These include pipecuronium, doxacurium, cisatracurium, and rapacuronium. Although not all remain in clinical use today, each represented an advance or improvement in at least one aspect over its predecessors. Still other NMBDs, such as CW 002[11] and CW 1759-50[11a,11b] are undergoing investigation.

NMBDs should be administered only to anesthetized individuals to provide relaxation of skeletal muscles. Because this class of drugs lacks analgesic or amnestic properties, NMBDs should not be administered to prevent patient movement. Awareness during surgery[12] and in the intensive care unit (ICU)[13] has been described in multiple publications. As stated by Cullen and Larson, "muscle relaxants given inappropriately may provide the surgeon with optimal [operating] conditions in…a patient[14] [who] is paralyzed but not anesthetized—a state that [is] wholly unacceptable for the patient."[15] Additionally, "muscle relaxants used to cover up deficiencies in total anesthetic management…represent an…inappropriate use of the valuable adjuncts to anesthesia."[15] Administration of NMBDs intraoperatively to maintain neuromuscular block requires that the time course of block be monitored and the depth of anesthesia be assessed continuously.

NMBDs have been integrated into most anesthetic techniques for major surgery and have become key components in the continuous improvement of safe anesthetic practice and the development of advanced surgical techniques. As earlier stated by Foldes and colleagues,[5] "…[the] first use of…muscle relaxants…not only revolutionized the practice of anesthesia but also started the modern era of surgery and made possible the explosive development of cardiothoracic, neurologic, and organ transplant surgery." Certainly, NMBDs are now used routinely to facilitate endotracheal intubation and mechanical ventilation, and are commonly used to maintain neuromuscular blockade through any number of different surgical procedures. This chapter reviews the pharmacology and clinical use of NMBDs and anticholinesterases in anesthesia and intensive care settings.

Principles of Action of Neuromuscular Blocking Drugs at the Neuromuscular Junction

A brief description of the physiology of neuromuscular blockade is presented in this chapter. A more comprehensive overview is provided in Chapter 12.

POSTJUNCTIONAL EFFECTS

Nicotinic acetylcholine receptors (nAChRs) belong to a large pentameric family of ligand-gated ion channel receptors that include the 5-hydoxytryptamine$_3$ (5-HT$_3$), glycine, and γ-aminobutyric acid (GABA) receptors. They are synthetized in muscle cells and anchored to the end plate membrane by a special protein called rapsyn. Development of innervation in the first weeks of life leads to the replacement of the γ subunit by ε subunit. In adult mammalian skeletal muscle, the nAChR is a pentameric complex of two α subunits in association with single β, δ, and ε subunits (Fig. 27.1). Stoichiometrically, the receptor is represented as α2βεδ, while organizationally it is αεαδβ.

The subunits are organized to form a transmembrane pore, or channel, as well as extracellular binding pockets for acetylcholine and other agonists or antagonists.[16] The receptors are clustered on the crests of the junctional folds; the receptor density in this area is 10,000 to 30,000/μm^2. Each of the two α subunits has an acetylcholine-binding site. These sites are located in pockets within the receptor protein, approximately 3.0 nm above the surface membrane at the interfaces of the α_H-ε and α_L-δ subunits.[17] αH and αL indicate the high- and low-affinity binding sites for dTc; the difference in affinity probably results from the contribution of the different neighboring subunits.18 For instance, the binding affinity of dTc for the αH-ε site is approximately 100 to 500 times higher than that for the αL-δ site.[18] The fetal nAChR contains a γ subunit instead of an adult ε subunit. Once activated by acetylcholine, the mature nAChR has a shorter opening time and a higher conductance to sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}) than the fetal nAChR, which has a smaller, single-channel conductance and a much longer open channel time.[16]

Functionally, the ion channel of the acetylcholine receptor is closed in the resting state. Simultaneous binding of two acetylcholine molecules to the α subunits is required to initiate conformational changes that open the channel. If one molecule of a nondepolarizer NMBD (i.e., a competitive antagonist) is bound to a subunit at the AChR, two agonist molecules of acetylcholine cannot bind simultaneously, and neuromuscular transmission is inhibited.[19]

Succinylcholine, a depolarizing NMBD, produces prolonged depolarization of the end plate region, which is similar to, but more persistent than, the depolarization induced by acetylcholine. This mechanism results in (1) desensitization of the nAChR, (2) inactivation of voltage-gated Na^+ channels at the neuromuscular junction, and (3) increases in K^+ permeability in the surrounding membrane.[19] The end results are failure of action potential generation and neuromuscular blockade.

The fetal nAChR is a low-conductance channel, in contrast to the high-conductance channel of the adult nAChR and upregulation of nAChRs found in states of functional

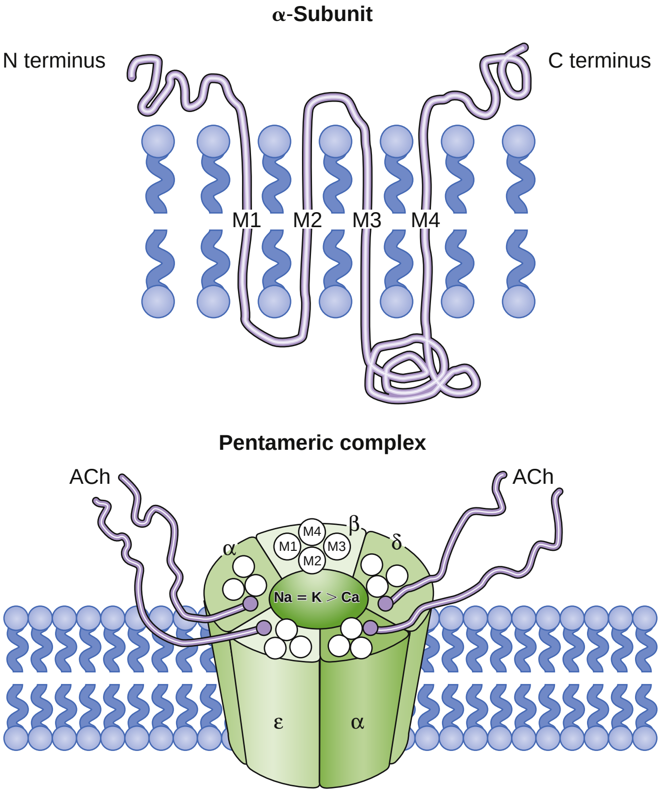

Fig. 27.1 Subunit composition of the nicotinic acetylcholine receptor (nAChR) in the end plate surface of adult mammalian muscle. The adult AChR is an intrinsic membrane protein with five distinct subunits $(\alpha_2\beta\delta\varepsilon)$. Each subunit contains four helical domains, labeled M_1 to M_4. The M_2 domain forms the channel pore. The *upper panel* shows a single α subunit with its N and C termini on the extracellular surface of the membrane lipid bilayer. Between the N and C termini, the α subunit forms four helices (M_1, M_2, M_3, and M_4), which span the membrane bilayer. The *lower panel* shows the pentameric structure of the nAChR of adult mammalian muscle. The N termini of two subunits cooperate to form two distinct binding pockets for acetylcholine. These pockets occur at the ε-α and the δ-α subunit interface. The M_2 membrane-spanning domain of each subunit lines the ion channel. The doubly liganded ion channel has equal permeability to sodium *(Na)* and potassium *(K)*; calcium *(Ca)* contributes approximately 2.5% to the total permeability. (From Naguib M, Flood P, McArdle JJ, et al. Advances in neurobiology of the neuromuscular junction: implications for the anesthesiologist. *Anesthesiology*. 2002;96:202–231, with permission from *Anesthesiology*.)

or surgical denervation is characterized by the spreading of predominantly fetal-type nAChRs. These receptors are resistant to nondepolarizing NMBDs and are more sensitive to succinylcholine.[20-22]

PREJUNCTIONAL EFFECTS

Prejunctional receptors are involved in the modulation of acetylcholine release in the neuromuscular junction. The existence of both nicotinic and muscarinic receptors on the motor nerve endings has been described. Prejunctional nicotinic receptors are activated by acetylcholine and function in a positive-feedback control system, which could mediate mobilization of the reserve store into the readily releasable store in case of high-frequency stimulation; this mobilization serves to maintain availability of acetylcholine when demand for it is high (e.g., during tetanic stimulation).[23] These presynaptic receptors are $\alpha_3\beta_2$ neuronal subtype receptors. Although most nondepolarizing NMBDs have a distinct affinity for the $\alpha_3\beta_2$ cholinergic receptor, succinylcholine lacks this affinity. The action of nondepolarizing versus depolarizing NMBDs at this neuronal cholinergic receptor explains the typical fade phenomenon after any nondepolarizing drugs, and the lack of such effect in the clinical dose range for succinylcholine. The G-protein–coupled muscarinic receptors also are involved in the feedback modulation of acetylcholine release.24 The prejunctional M1 and M2 receptors are involved in facilitation and inhibition of acetylcholine release, respectively, by modulating Ca2+ influx.[24] The prejunctional nicotinic receptors are involved with mobilization of acetylcholine but not directly with its release process.[25] Hence, blockade of the prejunctional nicotinic receptors by nondepolarizing NMBDs prevents acetylcholine from being made available fast enough to support tetanic or train-of-four (TOF) stimulation. In contrast, the prejunctional muscarinic receptors are involved with up-modulation or down-modulation of the release mechanism.

Succinylcholine

Fig. 27.2 Structural relationship of succinylcholine, a depolarizing neuromuscular blocking drug, and acetylcholine. Succinylcholine consists of two acetylcholine molecules linked through the acetate methyl groups. Like acetylcholine, succinylcholine stimulates nicotinic receptors at the neuromuscular junction.

Pharmacology of Succinylcholine

STRUCTURE-ACTIVITY RELATIONSHIPS

All NMBDs contain quaternary ammonium compounds and as such are structurally closely related to acetylcholine. Positive charges at the quaternary ammonium sites of NMBDs mimic the quaternary nitrogen atom of acetylcholine and are the structural reason for the attraction of these drugs to muscle- and neuronal-type nAChRs at the neuromuscular junction. These receptors are also located at other sites throughout the body where acetylcholine is the transmitter. These sites include the neuronal-type nicotinic receptors in autonomic ganglia and as many as five different muscarinic receptors on both the parasympathetic and sympathetic sides of the autonomic nervous system. In addition, populations of neuronal nicotinic and muscarinic receptors are located prejunctionally at the neuromuscular junction.[19]

The depolarizing NMBD, succinylcholine, is composed of two molecules of acetylcholine linked through the acetate methyl groups (Fig. 27.2). As described by Bovet,[26] succinylcholine is a small, flexible molecule, and like the natural ligand acetylcholine, succinylcholine stimulates cholinergic receptors at the neuromuscular junction and muscarinic autonomic sites, thus opening the ionic channel in the acetylcholine receptor.

PHARMACOKINETICS AND PHARMACODYNAMICS

Succinylcholine is the only available NMBD with a rapid onset of effect and an ultrashort duration of action. The ED_{95} (the dose causing on average 95% suppression of neuromuscular response) of succinylcholine is 0.51 to 0.63 mg/kg.[27] Using cumulative dose-response techniques, Kopman and coworkers estimated that its potency is far greater,[28] and it has an ED_{95} of less than 0.3 mg/kg.

Administration of 1 mg/kg of succinylcholine results in complete suppression of response to neuromuscular stimulation in approximately 60 seconds.[29] In patients with genotypically normal butyrylcholinesterase (also known as plasma cholinesterase or pseudocholinesterase), recovery to 90% muscle strength following administration of 1 mg/kg succinylcholine requires 9 to 13 minutes.[30]

The ultrashort duration of action of succinylcholine results from its rapid hydrolysis by butyrylcholinesterase to succinylmonocholine and choline. Butyrylcholinesterase has a large enzymatic capacity to hydrolyze succinylcholine, and only 10% of the intravenously administered drug reaches the neuromuscular junction.[31] The initial metabolite, succinylmonocholine, is a much weaker NMBD than succinylcholine and is metabolized much more slowly to succinic acid and choline. The elimination half-life of succinylcholine is estimated to be 47 seconds.[32]

Because little or no butyrylcholinesterase is present at the neuromuscular junction, the neuromuscular blockade induced by succinylcholine is terminated by its diffusion away from the neuromuscular junction into the circulation. Butyrylcholinesterase therefore influences the onset and duration of action of succinylcholine by controlling the rate at which the drug is hydrolyzed before it reaches, and after it leaves, the neuromuscular junction.

BUTYRYLCHOLINESTERASE ACTIVITY

Butyrylcholinesterase is synthesized by the liver and found in the plasma. The neuromuscular blockade induced by succinylcholine is prolonged when the concentration or activity of the enzyme is decreased. The activity of the enzyme refers to the number of substrate molecules (μmol) hydrolyzed per unit of time, and it is often expressed in International Units. Because the normal range of butyrylcholinesterase activity is quite large,[30] significant decreases in activity result in only modest increases in the time required to return to 100% of baseline muscle strength (Fig. 27.3).

Factors that lower butyrylcholinesterase activity include liver disease,[33] advanced age,[34] malnutrition, pregnancy, burns, oral contraceptives, monoamine oxidase inhibitors, echothiophate, cytotoxic drugs, neoplastic disease, anticholinesterase drugs,[35] tetrahydroaminacrine,[36] hexafluorenium,[37] and metoclopramide.[38] Bambuterol, a prodrug of terbutaline, produces marked inhibition of butyrylcholinesterase activity and causes prolongation of succinylcholine-induced blockade.[39] The β-blocker esmolol inhibits butyrylcholinesterase but causes only a minor prolongation of succinylcholine-induced blockade.[40]

Decreased butyrylcholinesterase enzyme activity is not a major concern in clinical practice because even large decreases in butyrylcholinesterase activity result in only modest increases in the duration of action of succinylcholine.

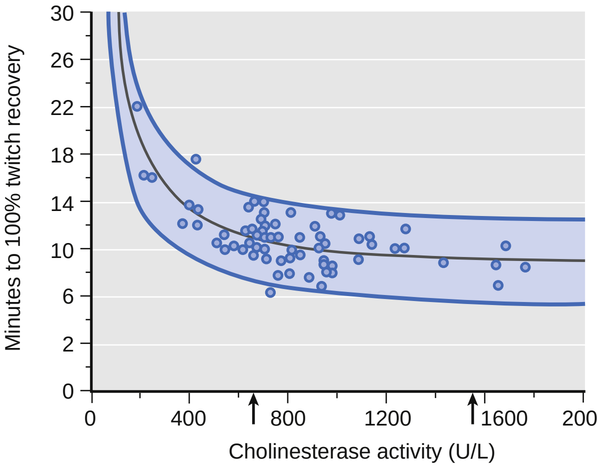

Fig. 27.3 Correlation between duration of succinylcholine neuromuscular blockade and butyrylcholinesterase activity. The normal range of activity lies between the *arrows*. (From Viby-Mogensen J. Correlation of succinylcholine duration of action with plasma cholinesterase activity in subjects with the genotypically normal enzyme. *Anesthesiology.* 1980;53:517–520.)

Even when butyrylcholinesterase activity is reduced to 20% of normal by severe liver disease, the duration of apnea after the administration of succinylcholine increases from a normal duration of 3 minutes to only 9 minutes. When glaucoma treatment with echothiophate decreased butyrylcholinesterase activity from 49% of control to no activity, the increase in the duration of neuromuscular blockade varied from 2 to 14 minutes. In no patient did the total duration of neuromuscular blockade exceed 23 minutes.[41]

DIBUCAINE NUMBER AND ATYPICAL BUTYRYLCHOLINESTERASE ACTIVITY

Succinylcholine-induced neuromuscular blockade can be significantly prolonged if a patient has an abnormal genetic variant of butyrylcholinesterase. Kalow and Genest discovered a variant that responded to dibucaine differently than it did to normal butyrylcholinesterase.[42] Dibucaine inhibits normal butyrylcholinesterase to a far greater extent than the abnormal enzyme. This observation led to the establishment of the dibucaine number. Under standardized test conditions, dibucaine inhibits the normal enzyme by approximately 80% and the abnormal enzyme by approximately 20% (Table 27.1). Many other genetic variants of butyrylcholinesterase have since been identified, although the dibucaine-resistant variants are the most important. A review by Jensen and Viby-Mogensen provides more detailed information on this topic.[43]

Although the dibucaine number indicates the genetic makeup of an individual with respect to butyrylcholinesterase, it does not measure the concentration of the enzyme in the plasma substrate. This is determined by measuring butyrylcholinesterase activity in plasma, and it may be influenced by comorbidities, medications, and genotype.

The molecular biology of butyrylcholinesterase is well understood. The amino acid sequence of the enzyme is known, and the coding errors responsible for most genetic variations have been identified.[43] Most variants result from a single amino acid substitution error or sequencing error at or near the active site of the enzyme. For example, in the

TABLE 27.1 Relationship Between Dibucaine Number and Duration of Succinylcholine or Mivacurium Neuromuscular Blockade

Type of Butyrylcholinesterase	Genotype	Incidence	Dibucaine Number*	Response to Succinylcholine or Mivacurium
Homozygous typical	$E_1^uE_1^u$	Normal	70-80	Normal
Heterozygous atypical	$E_1^uE_1^a$	1/480	50-60	Lengthened by 50%-100%
Homozygous atypical	$E_1^aE_1^a$	1/3200	20-30	Prolonged to 4-8 h

*The dibucaine number indicates the percentage of enzyme inhibited.

case of the "atypical" dibucaine-resistant (A) gene, a mutation occurs at nucleotide 209, where guanine is substituted for adenine. The resultant change in this codon causes substitution of glycine for aspartic acid at position 70 in the enzyme. In the case of the fluoride-resistant (F) gene, two amino acid substitutions are possible, namely, methionine for threonine at position 243, and valine for glycine at position 390. Table 27.1 summarizes many of the known genetic variants of butyrylcholinesterase: the amino acid substitution at position 70 is written as Asp ∅ Gly. New variants of butyrylcholinesterase genotypes continue to be discovered.[44]

SIDE EFFECTS

Cardiovascular Effects

Succinylcholine-induced cardiac dysrhythmias are many and varied. The drug stimulates cholinergic autonomic receptors on both sympathetic and parasympathetic ganglia[45] and muscarinic receptors in the sinus node of the heart. At low doses, both negative inotropic and chronotropic responses may occur. These responses can be attenuated by prior administration of atropine. With large doses of succinylcholine, these effects may become positive,[46] causing tachycardia. The clinical manifestation of generalized autonomic stimulation is the development of sinus bradycardia, junctional rhythms, and ventricular dysrhythmias. Clinical studies have described these dysrhythmias under various conditions in the presence of the intense autonomic stimulus of tracheal intubation. It is not entirely clear whether the cardiac irregularities are caused by the action of succinylcholine alone or by the added presence of extraneous autonomic stimulation. An in vitro study using ganglionic acetylcholine receptors subtype $\alpha_3\beta_4$ expressed in *Xenopus laevis* oocytes suggested that succinylcholine at clinically relevant concentrations had no effect on the expressed receptors.[47] Only high doses of succinylcholine caused inhibition of ganglionic acetylcholine receptors.[47] Whether or not these findings are applicable to clinical practice is unclear because the methodology (*X. laevis* oocytes expression model) has no clinical equivalent.

Sinus Bradycardia. Stimulation of cardiac muscarinic receptors in the cardiac sinus node causes sinus bradycardia. This side effect is particularly problematic in individuals with predominantly vagal tone, such as in children who have not received atropine. Sinus bradycardia can occur in adults and appears more commonly after a second dose of the drug administered approximately 5 minutes after the initial dose.[48] The bradycardia may be prevented by administration of atropine, ganglion-blocking drugs, and nondepolarizing NMBDs.[49] The ability of these drugs to prevent bradycardia implies that direct myocardial effects, increased muscarinic stimulation, and ganglionic stimulation may all be involved in the bradycardic response. The greater incidence of bradycardia after a second dose of succinylcholine suggests that the hydrolysis products of succinylcholine (succinylmonocholine and choline) may sensitize the heart to a subsequent dose.

Nodal (Junctional) Rhythms. Nodal rhythms occur commonly following administration of succinylcholine. The mechanism responsible for this likely involves relatively greater stimulation of muscarinic receptors in the sinus node, thus suppressing the sinus mechanism and allowing the emergence of the atrioventricular node as the pacemaker. The incidence of junctional rhythm is greater after a second dose of succinylcholine, and may be prevented by prior administration of dTc.[49]

Ventricular Dysrhythmias. Under stable anesthetic conditions, succinylcholine decreases the threshold of the ventricle to catecholamine-induced dysrhythmias in monkeys and dogs. Circulating catecholamine concentrations increase fourfold, and K^+ concentrations increase by one third, following succinylcholine administration in dogs.[50] Similar increases in catecholamine levels occur following administration of succinylcholine to humans.[51] Other autonomic stimuli, such as endotracheal intubation, hypoxia, hypercarbia, and surgery, may be additive to the effect of succinylcholine. The possible influence of drugs such as digitalis, tricyclic antidepressants, monoamine oxidase inhibitors, exogenous catecholamines, and anesthetic drugs such as halothane, which may lower the ventricular threshold for ectopic activity or increase the arrhythmogenic effect of the catecholamines, should also be considered. Ventricular escape beats may also occur as a result of severe sinus bradycardia and atrioventricular nodal slowing secondary to succinylcholine administration. The incidence of ventricular dysrhythmias is further increased by the release of K^+ from skeletal muscle as a consequence of the depolarizing action of the drug.

Hyperkalemia

The administration of succinylcholine to an otherwise healthy individual increases the plasma K^+ levels by approximately 0.5 mEq/dL. This slight increase in K^+ is well tolerated by most individuals and generally does not cause dysrhythmias. The increase in K^+ results from the depolarizing action of succinylcholine. With activation of the acetylcholine channels, movement of Na^+ into the cells is accompanied by movement of K^+ out of the cells.

Patients with renal failure are no more susceptible to an exaggerated response to succinylcholine than are those with normal renal function.[52] Patients who have uremic neuropathy may possibly be susceptible to succinylcholine-induced hyperkalemia, although the evidence supporting this view is scarce.[52,53,53a]

However, severe hyperkalemia may follow the administration of succinylcholine to patients with severe metabolic acidosis and hypovolemia.[54] In experimental animals (rabbit), the combination of metabolic acidosis and hypovolemia results in a high resting K^+ level and an exaggerated hyperkalemic response to succinylcholine.[55] In this situation, the K^+ originates from the gastrointestinal tract, rather than from muscle.[56] In patients with metabolic acidosis and hypovolemia, correction of the acidosis by hyperventilation and sodium bicarbonate administration should be attempted before succinylcholine administration. Should severe hyperkalemia occur, it can be treated with immediate hyperventilation, infusion of 500-1,000 mg calcium chloride or calcium gluconate over 3 minutes intravenously, and 10 units of regular insulin in 50 mL of 50% glucose for adults or, for children, 0.15 units/kg of regular insulin in 1.0 mL/kg of 50% glucose intravenously.

Kohlschütter and associates found that four of nine patients with severe abdominal infections had an increase in serum K^+ levels of as much as 3.1 mEq/L after succinylcholine administration.[57] The likelihood of a hyperkalemic response to succinylcholine increases in patients who have had intraabdominal infections for longer than 1 week.

Stevenson and Birch described a single, well-documented case of a marked hyperkalemic response to succinylcholine in a patient with a closed head injury without peripheral paralysis.[58]

Hyperkalemia after administration of succinylcholine is also a risk in patients who have had physical trauma.[59] The risk of hyperkalemia occurs 1 week after the injury, at which time a progressive increase in serum K^+ occurs during an infusion of succinylcholine. The risk of hyperkalemia can persist. Three weeks after injury, three of the patients studied in this series, who had especially severe injuries, became markedly hyperkalemic with an increase in serum K^+ of more than 3.6 mEq/L. Birch and coworkers also found that the prior administration of 6 mg of dTc prevented the hyperkalemic response to succinylcholine.[59] In the absence of infection or persistent degeneration of tissue, a patient is likely susceptible to the hyperkalemic response for at least 60 days after massive trauma or until adequate healing of damaged muscle has occurred.

Additionally, patients with conditions that result in the proliferation of extrajunctional acetylcholine receptors, such as upper or lower motor denervation, immobilization, burn injuries, and neuromuscular disease, are likely to have an exaggerated hyperkalemic response following the administration of succinylcholine. The response of patients with neuromuscular disease to NMBDs is reviewed in detail later in this chapter. Some of these disease states include cerebrovascular accident with resultant hemiplegia or paraplegia, muscular dystrophies, and Guillain-Barré syndrome. The hyperkalemia following administration of succinylcholine may be severe enough that cardiac arrest ensues. For a review of succinylcholine-induced hyperkalemia in acquired pathologic states, see Martyn and Richtsfeld.[22]

Increased Intraocular Pressure

Succinylcholine may cause an increase in intraocular pressure (IOP). The increased IOP develops within 1 minute of injection, peaks at 2 to 4 minutes, and subsides by 6 minutes.[60] The mechanism by which succinylcholine increases IOP has not been clearly defined, but it is known to involve contraction of tonic myofibrils and/or transient dilatation of choroidal blood vessels. Sublingual administration of nifedipine may attenuate the increase in IOP caused by succinylcholine, a finding suggesting a circulatory mechanism.[61] Despite this increase in IOP, the use of succinylcholine for eye operations is not contraindicated unless the anterior chamber is open. Although Meyers and colleagues were unable to confirm the efficacy of small (0.09 mg/kg) doses of dTc (“precurarization”) in attenuating increases in IOP following succinylcholine,[62] numerous other investigators have found that prior administration of a small dose of nondepolarizing NMBD (e.g., 3 mg of dTc or 1 mg of pancuronium) prevents a succinylcholine-induced increase in IOP.[63] Furthermore, Libonati and associates described the anesthetic management of 73 patients with penetrating eye injuries who received succinylcholine.[64] Among these 73 patients, no extrusion of vitreous occurred. Thus, despite the potential concerns, the use of succinylcholine in patients with penetrating eye injuries, after pretreatment with a nondepolarizing NMBD and with a carefully controlled rapid-sequence induction of anesthesia, can be considered. Succinylcholine is only one of many factors that may increase IOP.[62] Other factors include endotracheal intubation and “bucking” on the endotracheal tube once it is positioned. Of prime importance in minimizing the chance of increasing IOP is ensuring that the patient is well anesthetized and is not straining or coughing. For instance, coughing, vomiting and maximal forced lid closure may induce increases in intraocular pressure that are 3-4 times greater (60-90 mm Hg) than those induced by succinylcholine administration.[63a] Because a nondepolarizing NMBD with a rapid onset of effect, rocuronium, is available, it is possible to perform a rapid sequence induction of anesthesia and endotracheal intubation without administering succinylcholine. Finally, should a patient become too lightly anesthetized during intraocular surgery, succinylcholine should not be given to immobilize the patient. Rather, the surgeon should be asked to pause while anesthesia is deepened. If necessary, the depth of neuromuscular blockade can also be increased with nondepolarizing NMBDs.

Increased Intragastric Pressure

Unlike the rather consistent increase in IOP following administration of succinylcholine, increases in intragastric pressure (IGP) are much more variable. The increase in IGP from succinylcholine is presumed to result from fasciculations of the abdominal skeletal muscle. This is not surprising because more coordinated abdominal skeletal muscle activity (e.g., straight-leg raising) may increase the IGP to values as high as 120 cm H_2O (88 mm Hg). In addition to skeletal muscle fasciculations, the acetylcholine-like effect of succinylcholine may be partly responsible for the observed increases in IGP. Greenan observed consistent increases in IGP of 4 to 7 cm H_2O (3-5 mm Hg) with direct vagal stimulation.[65]

Miller and Way found that 11 of 30 patients had essentially no increase in IGP after succinylcholine administration, yet 5 of the 30 had an increase in IGP of greater than 30 cm H_2O (22 mm Hg).[66] The increase in IGP from succinylcholine appeared to be related to the intensity of the fasciculations of the abdominal skeletal muscles. Accordingly, when fasciculations were prevented by prior administration of a nondepolarizing NMBD, no increase in IGP was observed.

Whether the increases in IGP following succinylcholine administration are sufficient to cause incompetence of the gastroesophageal junction are debatable. Generally, an IGP greater than 28 cm H_2O (21 mm Hg) is required to overcome the competence of the gastroesophageal junction. However, when the normal oblique angle of entry of the esophagus into the stomach is altered, as may occur with pregnancy or an abdomen distended by ascites, bowel obstruction, or a hiatus hernia, the IGP required to cause incompetence of the gastroesophageal junction is frequently less than 15 cm H_2O (11 mm Hg).[66] In these circumstances, regurgitation of stomach contents following succinylcholine administration is a distinct possibility, and precautionary measures should be taken to prevent fasciculations. Endotracheal intubation may be facilitated with administration of either a nondepolarizing NMBD or a defasciculating dose of nondepolarizing relaxant before succinylcholine use. Although the increase in IGP from succinylcholine is well documented, the evidence of clinical harm is not clear.

Succinylcholine does not increase IGP appreciably in infants and children. This may be related to the minimal or absent fasciculations from succinylcholine in these young patients.[67]

Increased Intracranial Pressure

Succinylcholine has the potential to increase intracranial pressure.[68] The mechanisms and clinical significance of this transient increase are unknown, but pretreatment with nondepolarizing NMBDs prevents intracranial pressure increases.[68]

Myalgia

The incidence of muscle pain following administration of succinylcholine varies widely, from 0.2% to 89%.[69] Muscle pain occurs more frequently after minor surgery, especially in women and in ambulatory, rather than bedridden, patients.[70] Waters and Mapleson postulated that pain is secondary to damage produced in muscle by the unsynchronized contractions of adjacent muscle fibers just before the onset of paralysis.[70] This concept has been substantiated by finding myoglobinemia and increases in serum creatine kinase following succinylcholine administration.[71] Prior administration of a small ("defasciculating") dose of a nondepolarizing NMBD clearly prevents fasciculations from succinylcholine.[71] The efficacy of this approach in preventing muscle pain is not clear; however, most investigators report that pretreatment with a nondepolarizing NMBD has minimal effect.[69] Pretreatment with a prostaglandin inhibitor (e.g., lysine acetyl salicylate) has been shown effective in decreasing the incidence of muscle pain after succinylcholine.[72] This finding suggests a possible role for prostaglandins and cyclooxygenases in succinylcholine-induced myalgias. Other investigators have found that myalgias following outpatient laparoscopic surgery (and atracurium administration) occur even in the absence of succinylcholine.[73] Other investigators reported a significant reduction in postoperative myalgia in elective oral surgery patients pretreated with rocuronium (20%) compared with vecuronium (42%) and placebo (70%).[73a]

Masseter Muscle Rigidity

An increase in tone of the masseter muscle is a frequent response to succinylcholine in adults[74] as well as in children.[75] Several studies have reported that an increase in masseter muscle tone of up to 500 g lasting 1 to 2 minutes is a normal finding in adults.[76] Most cases of the so-called masseter muscle rigidity (MMR) may represent simply the extreme of a spectrum of muscle tension changes that occur in response to succinylcholine. Meakin and associates suggested that the high incidence of spasm in children may result from inadequate dosage of succinylcholine.[75] In all likelihood, this increase in tone is an exaggerated contractile response at the neuromuscular junction and cannot be used to establish a diagnosis of malignant hyperthermia. Although an increase in tone of the masseter muscle may be an early indicator of malignant hyperthermia, this finding is not consistently associated with that syndrome.[76] Currently, no indication exists to change to a "nontriggering" anesthetic technique in instances of isolated MMR.[77]

Anaphylaxis

There is some controversy concerning the incidence of anaphylaxis following succinylcholine. The incidence of anaphylactic reactions may be close to 0.06%. Almost all cases of anaphylaxis have been reported in Europe or Australia. When the muscle relaxant cross-links with IgE, degranulation and release of histamine, neutrophil chemotactic factor, and platelet-activating factor occur. The release of these mediators can induce cardiovascular collapse, bronchospasm, and skin reaction.[77a] Patients with a history of anaphylactic reaction to succinylcholine may exhibit a cross-reaction, at least in vitro, with other NMBDs. The cross-reactivity is related to the common structural features of these drugs, all of which contain quaternary ammonium ions.

CLINICAL USES

In spite of its many adverse effects, succinylcholine remains in clinical use. Its popularity is likely the result of its rapid onset of effect, the profound depth of neuromuscular blockade it produces, and its short duration of action. Succinylcholine is not used as regularly as in the past for routine endotracheal intubation, but it is still a muscle relaxant frequently used for rapid-sequence induction of anesthesia and tracheal intubation. Although 1.0 mg/kg of succinylcholine is recommended to facilitate endotracheal intubation at 60 seconds, as little as 0.5 to 0.6 mg/kg may result in adequate intubating conditions 60 seconds after administration.[78] Reduction in the succinylcholine dose from 1.0 to 0.6 mg/kg decreases the incidence of hemoglobin desaturation but does not shorten the time to spontaneous diaphragmatic movements.[79] Decreasing the dose of succinylcholine is appealing as long as it does not interfere with provision of adequate conditions for endotracheal intubation and subsequent adequate ventilation.[79]

Typically, after administering succinylcholine for tracheal intubation, a nondepolarizing NMBD is given to maintain neuromuscular blockade. Prior administration of succinylcholine enhances the depth of blockade caused by a subsequent dose of nondepolarizing NMBD.[80,81] However, the effect on duration of action is variable. Succinylcholine has no effect on the duration of pancuronium,[82] but it increases the duration of atracurium and rocuronium.[80,83] The reasons for these differences are not clear.

With administration of large doses of succinylcholine, the nature of the block, as determined by a monitor of neuromuscular blockade, changes from that of a depolarizing drug (phase 1 block) to that of a nondepolarizing drug (phase 2 block). Clearly, both the dose and the duration of administration of succinylcholine contribute to this change. The relative contribution of each factor has not been established, however.

Posttetanic potentiation and fade in response to TOF and tetanic stimuli can be demonstrated after bolus administration of different doses of succinylcholine.[84] It seems that some characteristics of phase 2 blockade are evident from an initial dose (i.e., as small as 0.3 mg/kg) of succinylcholine.[84] Fade in response to TOF stimulation has been attributed to the presynaptic effects on NMBDs. The etiology of the appearance of fade phenomenon in the TOF response following excessive administration of succinylcholine has been suggested to be dependent on a concentration-dependent affinity for succinylcholine to the presynaptic $\alpha_3\beta_2$ neuronal subtype AChR in concentrations exceeding the normal clinical concentration range seen after routine doses.[47]

INTERACTIONS WITH ANTICHOLINESTERASES

Neostigmine and pyridostigmine inhibit butyrylcholinesterase, as well as acetylcholinesterase. If succinylcholine is administered after antagonism of residual neuromuscular block, as it may be with postextubation laryngospasm, the effect of succinylcholine will be pronounced and significantly prolonged. The effect of succinylcholine (1 mg/kg) was prolonged from 11 to 35 minutes when it was given 5 minutes after administration of neostigmine (5 mg).[35] Ninety minutes after neostigmine administration, butyrylcholinesterase activity will have returned to less than 50% of its baseline value.

Nondepolarizing Neuromuscular Blocking Drugs

The use of NMBDs in anesthesia has its origin in the arrow poisons or curares of South American Indians. Several nondepolarizing NMBDs were purified from naturally occurring sources. For example, dTc can be isolated from the Amazonian vine *Chondodendron tomentosum*. Similarly, the intermediates for the production of metocurine and alcuronium, which are semisynthetic, are obtained from *Chondodendron* and *Strychnos toxifera*. Malouetine, the first steroidal NMBD, was originally isolated from *Malouetia bequaertiana*, which grows in the jungles of the Democratic Republic of Congo in central Africa. The NMBDs pancuronium, vecuronium, pipecuronium, rocuronium, rapacuronium, atracurium, doxacurium, mivacurium, cisatracurium, gantacurium, and gallamine are all synthetic compounds.

Available nondepolarizing NMBDs can be classified according to chemical class, based on structure (steroids, benzylisoquinoliniums, fumarates, and other compounds), or, alternatively, according to onset or duration of action (long-, intermediate-, and short-acting drugs) of equipotent doses (Table 27.2).

STRUCTURE-ACTIVITY RELATIONSHIPS

Nondepolarizing NMBDs were originally classified by Bovet as pachycurares,[26] or bulky molecules having the amine functions incorporated into rigid ring structures. Two extensively studied chemical series of synthetic nondepolarizing NMBDs are the aminosteroids, in which the interonium distance is maintained by an androstane skeleton, and the benzylisoquinolinium series, in which the distance is maintained by linear diester-containing chains or, in the case of curare, by benzyl ethers. For a detailed account on structure-activity relationships, see Lee.[85]

Benzylisoquinolinium Compounds

dTc is an NMBD in which the amines are present in the form of two benzyl substituted tetrahydroisoquinoline structures (Fig. 27.4). Using nuclear magnetic resonance spectroscopy and methylation–demethylation studies, Everett and associates demonstrated that dTc contains three *N*-methyl groups.[86] One amine is quaternary (i.e., permanently charged with four nitrogen substituents), and the other is tertiary (i.e., pH-dependent charge with three nitrogen substituents). At physiologic pH, the tertiary nitrogen is protonated so that it is positively charged. The structure-activity relationships of the bis-benzylisoquinolines (see Fig. 27.4) have been described by Waser[87] and by Hill and associates,[88] and these relationships are as follows:

1. The nitrogen atoms are incorporated into isoquinoline ring systems. This bulky molecule favors a nondepolarizing rather than a depolarizing activity.

TABLE 27.2 Classification of Nondepolarizing Neuromuscular Blockers According to Duration of Action (Time to T1 = 25% of Control) after Twice the Dose Causing on Average 95% Suppression of Neuromuscular Response

	CLINICAL DURATION			
	Long-acting (>50 min)	**Intermediate-acting (20-50 min)**	**Short-acting (10-20 min)**	**Ultrashort-acting (<10 min)**
Steroidal compounds	Pancuronium	Vecuronium Rocuronium		
Benzylisoquinolinium compounds	*d*-Tubocurarine	Atracurium Cisatracurium	Mivacurium	
Asymmetric mixed-onium fumarates		CW 002		Gantacurium

Most nondepolarizing neuromuscular blockers are bisquaternary ammonium compounds. *d*-Tubocurarine, vecuronium, and rocuronium are monoquaternary compounds.

T1, First twitch of train-of-four.

2. The interonium distance (distance between charged amines) is approximately 1.4 nm.
3. Both the ganglion-blocking and the histamine-releasing properties of dTc probably result from the presence of the tertiary amine function.
4. When dTc is methylated at the tertiary amine and at the hydroxyl groups, the result is metocurine, a compound of greater potency (by a factor of two in humans) with much weaker ganglion-blocking and histamine-releasing properties than dTc (see Fig. 27.4). Metocurine contains three additional methyl groups, one of which quaternizes the tertiary nitrogen of dTc; the other two form methyl ethers at the phenolic hydroxyl groups.
5. Bisquaternary compounds are more potent than their monoquaternary analogues. The bisquaternary derivative of dTc, chondocurine, is more than twice as potent as dTc (see Fig. 27.4).

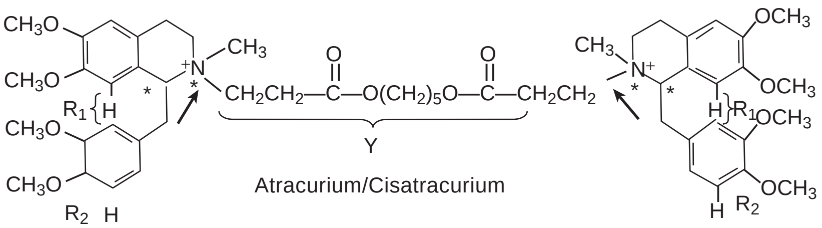
6. Substitution of the methyl groups on the quaternary nitrogen with bulkier groups causes a reduction in both potency and duration of action.

Atracurium is a bis-benzyltetrahydroisoquinolinium with isoquinolinium nitrogens connected by a diester-containing hydrocarbon chain (Fig. 27.5). The presence (in duplicate) of two-carbon separations between quaternary nitrogen and ester carbonyl renders it susceptible to the Hofmann elimination reaction.[89] The compound can also undergo ester hydrolysis. In a Hofmann elimination reaction, a quaternary ammonium group is converted into a tertiary amine through cleavage of a carbon-nitrogen bond. This is a pH- and temperature-dependent reaction in which higher pH and temperature favor elimination.

Atracurium has 4 chiral centers at each of the chiral carbons adjacent to the two amines. It is composed of 10 isomers.[89] These isomers have been separated into three geometric isomer groups that are designated *cis-cis*, *cis-trans*, and *trans-trans* according to their configuration about the tetrahydroisoquinoline ring system.[89] The ratio of the *cis-cis*, *cis-trans*, and *trans-trans* isomers is approximately 10:6:1, corresponding to 50% to 55% *cis-cis*, 35% to 38% *cis-trans*, and 6% to 7% *trans-trans* isomers.

Cisatracurium, the 1R *cis*–1′R *cis* isomer of atracurium, comprises approximately 15% of atracurium by weight but more than 50% in terms of neuromuscular blocking activity (see Fig. 27.5). R designates the absolute stereochemistry of the benzyl tetrahydroisoquinoline rings, and *cis* represents the relative geometry of the bulky dimethoxy and 2-alkyester groups at C(1) and N(1), respectively.[90,91] Like atracurium, cisatracurium undergoes Hofmann elimination. It is approximately four times as potent as atracurium, and in contrast to atracurium, it does not cause histamine release,[90,92] thus indicating that histamine release may be stereospecific.[90,93]

Mivacurium differs from atracurium by the presence of an additional methylated phenolic group (see Fig. 27.5). Compared with other isoquinolinium NMBDs, the interonium chain of mivacurium is longer (16 atoms).[88] Mivacurium consists of a mixture of three stereoisomers.[94] The two most active are the *trans-trans* and *cis-trans* isomers (57% and



$$-CH_2CH_2-\overset{\overset{O}{\|}}{C}-O(CH_2)_5O-\overset{\overset{O}{\|}}{C}-CH_2CH_2-$$

37% weight/weight, respectively), which are equipotent; the *cis-cis* isomer (6% weight/weight) has only one tenth the neuromuscular blocking activity of the more potent isomers in cats and monkeys.[94] Mivacurium is metabolized by butyrylcholinesterase to a monoester and a dicarboxylic acid at 70% to 88% the rate at which succinylcholine is metabolized by the same enzyme.[9]

Steroidal Neuromuscular Blockers

For the steroidal compounds to have neuromuscular blocking potential, it is likely that one of the compound's two nitrogen atoms be quaternized. The presence of an acetyl ester (acetylcholine-like moiety) facilitates their interaction with nAChRs at the postsynaptic muscle membrane.

Pancuronium is characterized by the presence of two acetyl ester groups on the A and D rings of the steroidal molecule. Pancuronium is a potent NMBD with vagolytic properties. It is also an inhibitor of butyrylcholinesterase (Fig. 27.6).[95] Deacetylation at the 3 or 17 positions decreases its potency.[96]

Vecuronium, in which the 2-piperidine substituent is not methylated, is the *N*-demethylated derivative of pancuronium (see Fig. 27.6).[7] At physiologic pH, the tertiary amine is largely protonated, as it is in dTc. The minor molecular modification results in the following: (1) a slight increase in the potency when compared with pancuronium; (2) a marked reduction in its vagolytic properties; (3) molecular instability in solution; and (4) increased lipid solubility, which results in a greater biliary elimination of vecuronium than pancuronium.[88]

Vecuronium is degraded by the hydrolysis of the acetyl esters at the C3 and the C17 positions. Hydrolysis at the C3 position is the primary degradation pathway because the acetate at the 3 position is more susceptible to hydrolysis in aqueous solutions than the acetate at the 17 position. This is because of the adjacent basic piperidine at the 2 position that facilitates hydrolysis of the 3-acetate. Therefore vecuronium cannot be prepared as a ready-to-use solution with a sufficient shelf life, even as a buffered solution. In contrast, the 2-piperidine of pancuronium is quaternized and no longer alkaline and therefore does not facilitate hydrolysis of the 3-acetate.

Rocuronium lacks the acetyl ester that is found in the A ring of the steroid nucleus of pancuronium and vecuronium (see Fig. 27.6). The introduction of cyclic substituents other than piperidine at the 2 and 16 positions results in a compound with a more rapid onset of effect than vecuronium or pancuronium.[97] The methyl group attached to the quaternary nitrogen of vecuronium and pancuronium is replaced by an allyl group in rocuronium. As a result of this change, rocuronium is approximately 6 and 10 times less potent than pancuronium and vecuronium, respectively.[97-99] The replacement of the acetyl ester attached to the A ring by a hydroxy group means that rocuronium is stable in solution. At room temperature, rocuronium is stable for 60 days. In contrast, pancuronium is stable for 6 months. The reason for this difference in shelf life is related to the fact that rocuronium is terminally sterilized in manufacturing, and pancuronium is not. Terminal sterilization causes some degree of degradation.

Asymmetric Mixed-Onium Fumarates and Analogues

These compounds share some structural properties with mivacurium. Gantacurium and CW 002 represent a new

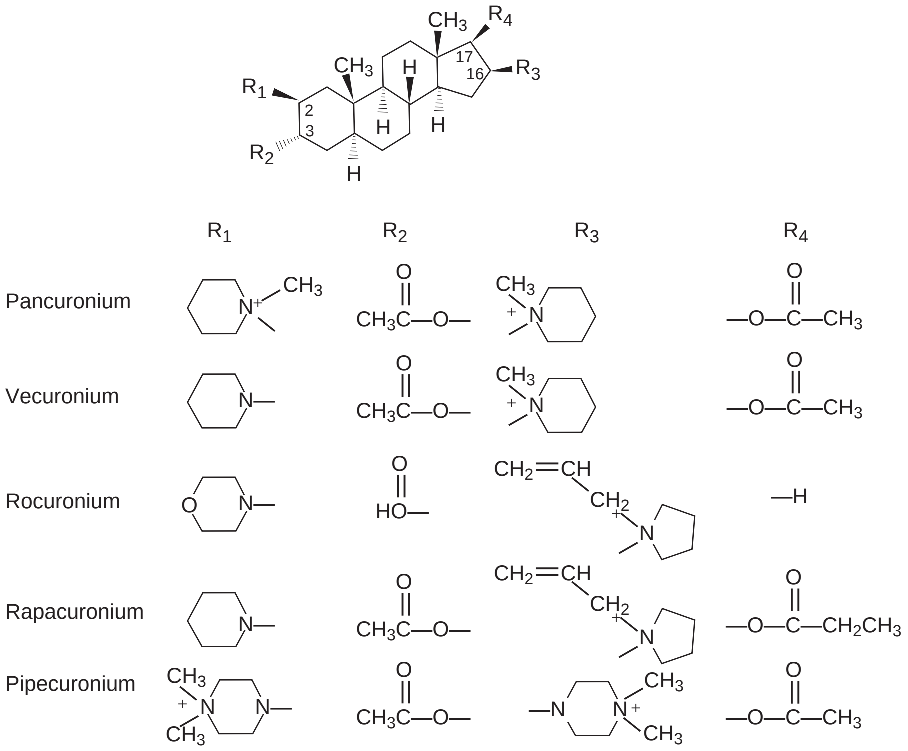

Fig. 27.6 Chemical structures of different steroidal neuromuscular blockers.

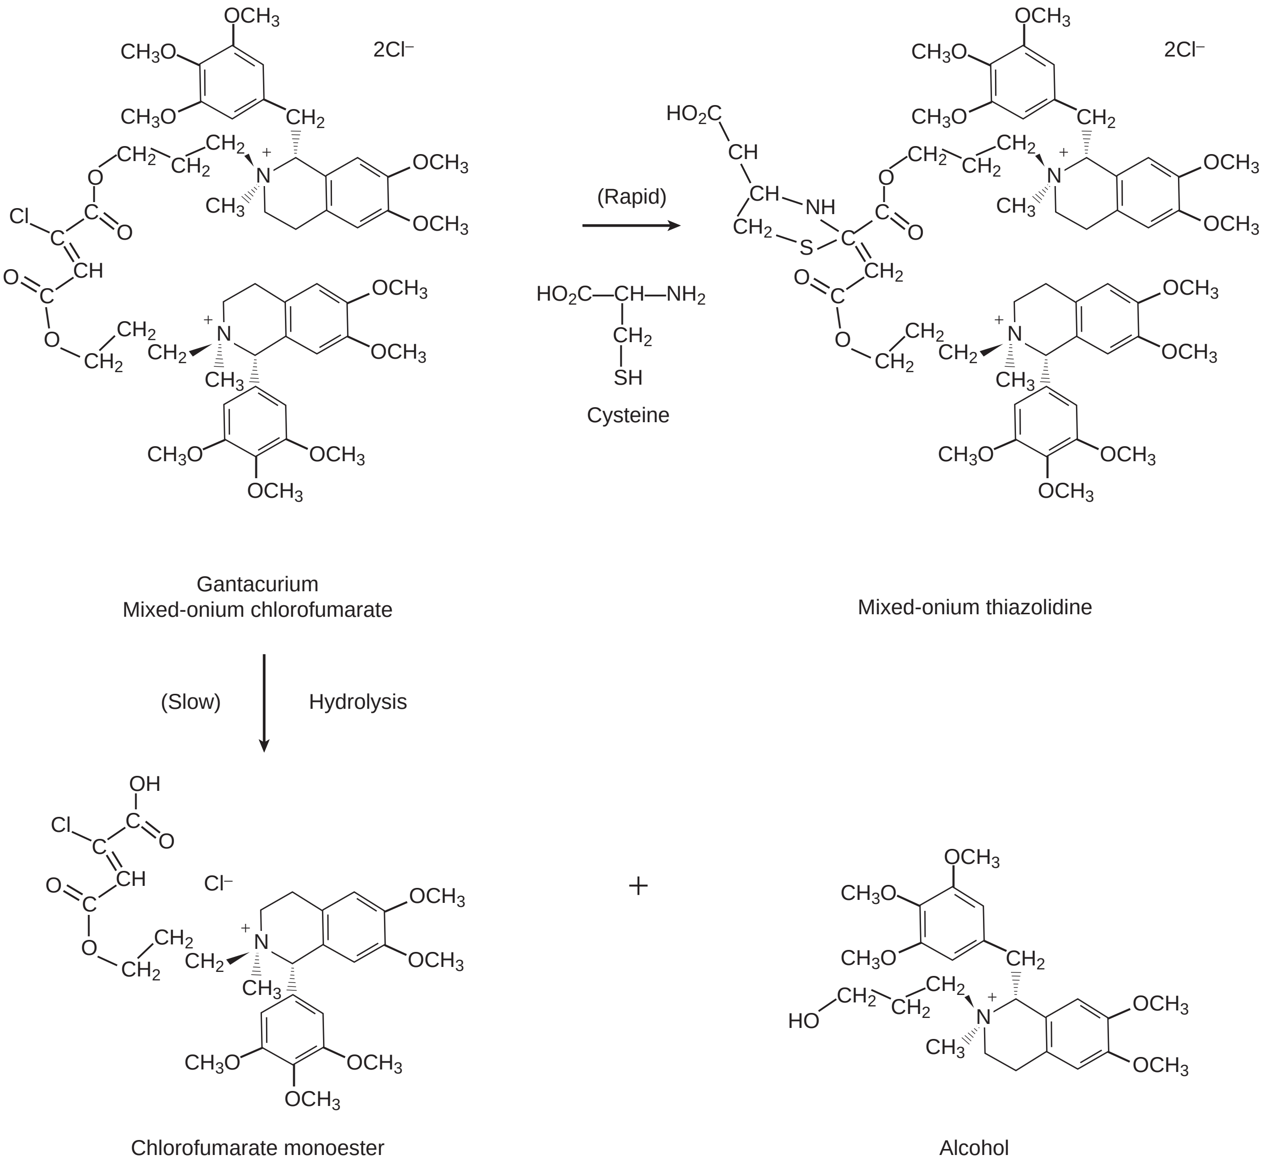

Fig. 27.7 Chemical structure of gantacurium (a mixed-onium chlorofumarate). In whole human blood, two pathways of deactivation occur, neither of which is enzymatic: (1) rapid formation of an apparently inactive cysteine adduction product, with cysteine replacing chlorine; and (2) slower hydrolysis of the ester bond adjacent to the chlorine substitution to chlorofumarate monoester and alcohol. (From Boros EE, Samano V, Ray JA, et al. Neuromuscular blocking activity and therapeutic potential of mixed-tetrahydroisoquinolinium halofumarates and halosuccinates in rhesus monkeys. *J Med Chem.* 2003;46:2502–2515.)

class of bisquaternary nondepolarizing NMBDs (Fig. 27.7). Gantacurium, an asymmetric mixed-onium chlorofumarate, is unique among nondepolarizing compounds in terms of its rapid onset of effect, its short duration of action, and its unique means of inactivation.[11,100] Because of the presence of three methyl groups between the quaternary nitrogen and oxygen atom at each end of the carbon chain, this compound does not undergo Hofmann elimination.[100]

Gantacurium has an ultrashort duration of action in human volunteers and in different animal species. In human volunteers receiving a nitrous oxide–opioid anesthetic, the ED_{95} of gantacurium is 0.19 mg/kg.[100] Onset of and recovery from block resemble those of succinylcholine. Following administration of approximately 2.5 times the ED_{95} dose, onset of maximal block occurs in 1.5 minutes. Spontaneous recovery to a TOF of 0.9 or greater occurs 10 minutes after administration of an ED_{95} dose, and complete spontaneous recovery occurs in 14 to 15 minutes after administration of doses ranging from 2 to 3.5 times the ED_{95}. Recovery is accelerated by administration of edrophonium at the beginning of spontaneous recovery. Transient hypotension and tachycardia occur following administration of doses three times the ED_{95} and greater, a finding suggesting that histamine release occurs with administration of these doses.[100]

Gantacurium appears to undergo two pathways of inactivation. One is a slower ester hydrolysis, and the second one, which occurs much more quickly, occurs through the adduction of cysteine, a nonessential amino acid, to create a new compound that can no longer bind to the nAChR of the neuromuscular junction.[101] This unique means of inactivation likely accounts for the drug's ultrashort duration of effect. It also provides a novel means of shortening recovery

TABLE 27.3 Dose-Response Relationships of Nondepolarizing Neuromuscular Blocking Drugs in Human Subjects

Data are the medians and ranges of reported values. ED_{50}, ED_{90}, and ED_{95} are the doses of each drug that produce, respectively, 50%, 90%, and 95% decrease in the force of contraction or amplitude of the electromyogram of the adductor pollicis muscle following ulnar nerve stimulation.

from gantacurium-induced neuromuscular block. Administration of L-cysteine (10 mg/kg) 1 minute after administration of gantacurium results in rapid return to complete neuromuscular function within 1 to 2 minutes.[102]

An analogue of the asymmetric fumarate gantacurium, CW 002 has been synthesized to undergo slower L-cysteine adduction. Because of its slower metabolism, it has an intermediate duration of action. In animals, it causes a nondepolarizing block that can be antagonized by neostigmine. Administration of L-cysteine 1 minute after administration of CW 002 effectively speeds recovery of neuromuscular function, whereas neostigmine does not.[22] Volunteer trials are required to determine whether onset, recovery, and ease of antagonism are improved over those using compounds that are currently available.

CW 011 (an asymmetrical maleate) is a nonhalogenated olefinic diester analogue of gantacurium[101] that can undergo L-cysteine adduction in animal models. Because this adduction reaction is slower than that of gantacurium, its duration of neuromuscular block is longer (approximately 21 minutes). Exogenous L-cysteine (50 mg/kg) administration can induce full recovery of neuromuscular block (after five times ED_{95} dose of CW 011) in 2 to 3 minutes.[101]

The clinical development of gantacurium was suspended in 2006, but since then, several other compounds similar to gantacurium have been tested. CW 1759-50 is a fast-onset, ultrashort-acting NMBA that is devoid of histaminoid side effects in animal testing.[11a,11b] CW 1759-50 is ultrashort acting because it is inactivated by plasma L-cysteine. Spontaneous recovery (5%-95% interval) from either bolus or infusion was similar (5-6 minutes), and reversal by L-cysteine required about 2 minutes.

POTENCY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKING DRUGS

Drug potency is commonly expressed by the dose-response relationship. The dose of an NMBD required to produce an effect (e.g., 50%, 90%, or 95% depression of baseline twitch height, commonly expressed as ED_{50}, ED_{90}, and ED_{95}, respectively) defines its potency.[9,98,103-114] The NMBDs have different potencies, as illustrated in Table 27.3 and Fig. 27.8. For factors affecting the potency of NMBDs, see the section on drug interactions later in this chapter. The dose-response relationship for nondepolarizing NMBDs is sigmoidal (see Fig. 27.8) and has been derived in various ways. The simplest method is to perform linear regression over the approximately linear portion of a semilogarithmic plot between 25% and 75% neuromuscular blockade. Alternatively, the curve can be subjected to probit or logit transformation to linearize it over its whole length, or the data can be subjected to nonlinear regression using the sigmoid E_{max} model of this form:

$$Effect\ (e) = F\left(dose_e^{\gamma},\ dose_e^{\gamma} + dose_{e50}^{\gamma}\right)$$

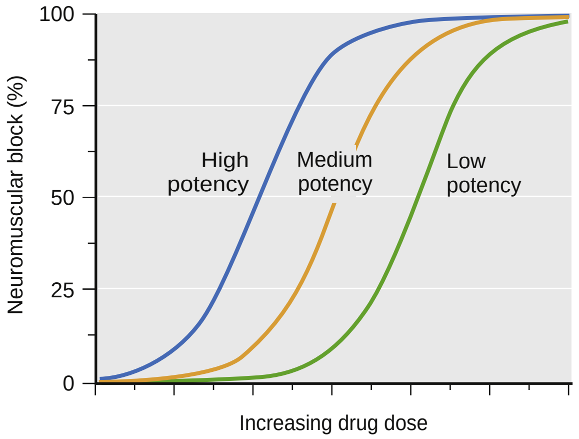

Fig. 27.8 Schematic representation of a semilogarithmic plot of a muscle-relaxant dose versus neuromuscular blockade. A drug of high potency is doxacurium, one of medium potency is atracurium, and one of low potency is gallamine. The graph illustrates that the relative potencies of the muscle relaxants span a range of approximately two orders of magnitude.

More complex models relating the concentration of NMBDs at the neuromuscular junction to their pharmacologic effect have been developed, and are discussed later.[115,116]

Factors that govern duration of action of NMBDs.

Onset

There is ample evidence that potent NMBDs have slower onset times than less potent drugs with similar physicochemical properties. These facts can be explained by the concept of the margin of safety. A critical number of receptors at the neuromuscular junction must be occupied before appearance of neuromuscular block, and at least 90% of the receptors must be occupied before block is complete at the adductor pollicis. When the drug reaches the synaptic cleft, most molecules will bind to receptors that are present with a high density. As the concentration of free drug decreases, more molecules are driven in and the process will continue until the concentrations of free drug within and outside the synaptic cleft are equal. When a potent drug is administered, fewer molecules are given than in a case of a less potent drug, and the onset will be slower compared to onset of lower potency NMBD.[116a] Nondepolarizing NMBDs of low potency (e.g., rocuronium) have more molecules to diffuse from the central compartment into the effect compartment. Once in the effect compartment, all molecules act promptly. Weaker binding of the low-potency drugs to receptors prevents buffered diffusion, a process that occurs with more potent drugs. Buffered diffusion causes repetitive binding and unbinding to receptors, thus keeping potent drugs in the neighborhood of the effector sites and potentially lengthening the duration of effect. This phenomenon is probably what contributes to the slower onset time for cisatracurium than atracurium. However, for very short-acting drugs, the ideal ED_{95} might be greater (0.5-1.0 mg/kg) because rapid metabolism in the plasma destroys some of the administered muscle relaxant before it reaches the neuromuscular junction. This phenomenon can explain the relatively slow onset time for mivacurium.

Plasma concentrations have only modest influence on onset time. Arterial plasma concentrations peak 25 to 35 seconds after administration, thus before onset of neuromuscular block. This paradox can be explained by assuming that the site of action, the neuromuscular junction, is represented by the effect compartment in which the concentration of the NMBD is directly related to the magnitude of neuromuscular blockade.[116b] The rate constant for transfer into the effect compartment is similar for most intermediate duration action NMBDs and corresponds approximately to neuromuscular junction blood flow divided by neuromuscular junction/plasma partition coefficient. Whatever muscle relaxant, the limiting factor appears to be the time required for the drug to reach the neuromuscular junction, which in turn depends on cardiac output, the distance of the muscle (and neuromuscular junction) from the central circulation, and muscle blood flow. Therefore in most cases, the onset time will be dependent on blood flow to muscle. Under normal circumstances, muscle blood flow increases when cardiac output increases, with a direct relationship between speed of onset and cardiac output. This may explain why infants and children have a faster onset of neuromuscular block, and elderly patients have a slower onset than younger individuals.

It is obvious that the intensity of maximum blockade is affected directly by the administered dose. However, when the dose increases in the subparalyzing range (that is, when maximum blockade is between 0% and 100%), time to reach maximum effect is dose-independent. This is because the time to peak concentration at the effect compartment is independent of the dose. When the administered dose, however, is sufficient to effect complete disappearance of neuromuscular response, time to maximum blockade becomes dose-dependent.

DURATION OF ACTION

Although it is commonly believed that the rate of decline of NMBD plasma concentrations during recovery from neuromuscular blockade determines the duration of action and the rate of recovery, further explanations are needed. It has been suggested that muscle blood flow is, to a certain extent, a limiting factor in the termination of action. For long-acting NMBDs, the dominant effect for the recovery from neuromuscular blockade is the rate of decrease of plasma concentration because there is pseudo-equilibrium between concentrations at the neuromuscular junction and plasma. Therefore changing blood flow will not affect the duration of action. For intermediate duration of action NMBD, after a single bolus dose, plasma concentrations decrease at a rate that differs slightly from the equilibrium half-life with muscle. It can induce a significant concentration gradient between neuromuscular junction and plasma during recovery, but provided that recovery rate is constant, the ratio of concentrations between the neuromuscular junction and plasma will remain relatively constant.

The most important factor is that the rate of decline of plasma concentration during recovery is not always related to the NMBD terminal half-life because after initial administration, plasma concentrations will decrease because of redistribution. It is only when redistribution will be complete that the decrease in plasma concentrations will be dependent on the terminal half-life and will decrease more slowly. For long-acting NMBD such as pancuronium, the recovery time will take place during the terminal half-life. In this situation the duration of action will be dependent on the rate of decrease of plasma concentrations. This is different for intermediate duration of action NMBDs. The terminal half-life of atracurium is around 20 minutes, whereas the elimination half-lives of both vecuronium and rocuronium are between 60 and 120 minutes. Although such differences can be observed, the duration of action and recovery from neuromuscular block of these three drugs are very similar. These apparent discrepancies can be explained by the fact that the distribution phase is the most important factor and extends for a much longer period than for long-acting NMBDs.[116c] If their duration of action and recovery rates are almost identical, it is due to the decrease of plasma concentrations to levels compatible with recovery during the redistribution phase.

CLINICAL MANAGEMENT

The main goal of neuromuscular blockade during induction of anesthesia includes paralysis of the vocal cords and muscles of the jaw to facilitate endotracheal intubation. Relaxation of the respiratory muscles, particularly the diaphragm, allows controlled ventilation. Paralysis of the abdominal muscles and the diaphragm is often required intraoperatively, particularly during abdominal, robotic, or laparoscopic surgery. During recovery from neuromuscular block, restoration of complete neuromuscular strength is essential to ensure adequate spontaneous ventilation with normal regulation of breathing during hypoxia and the patency of the musculature of the upper airway with maintained airway protection. The choice of the initial dose of NMBD, timing of readministration of NMBD, timing of administration of anticholinesterase, and interpretation of monitoring require an understanding of the varying sensitivities of different muscle groups to NMBDs.

Although the practice of administering an NMBD to facilitate tracheal intubation may be routine, it has been suggested that the combination of propofol with a rapid-acting opioid may provide good to excellent intubating conditions in most patients. However, relatively large doses of opioids are required to obtain satisfactory intubating conditions. Mencke and coworkers demonstrated that adding atracurium to a propofol-fentanyl induction regimen significantly improved the quality of intubating conditions and decreased the frequency of vocal cord lesions following intubation from 42% to 8%.[117] The rate of postoperative hoarseness was also significantly decreased to 16% from 44%.[117] Combes and associates confirmed that the use of NMBD for tracheal intubation decreased the incidence of adverse postoperative upper airway symptoms, resulted in better intubating conditions, and also reduced the rate of adverse hemodynamic effects caused by deeper levels of anesthesia.[118] Patients intubated without an NMBD had three to four times more Cormack scores of 3 to 4, and difficult intubation was more common (12% vs. 1%). In a cohort of more than 100,000 patients, Lundstrom and colleagues demonstrated that avoidance of NMBD was associated with more difficult tracheal intubation conditions compared with NMBD use, with an odds ratio of 1.5.[118a] A recent Cochrane review supported the use of an NMBD (vs. avoidance of NMBD) in order to create the best intubating conditions.[118b]

Several alternative approaches are available to enhance surgical relaxation when administration of additional NMBDs may be inappropriate. These options include increasing the depth of general anesthesia with a drug such as a volatile anesthetic or propofol, administering lidocaine, using regional anesthesia, positioning the patient properly on the operating table, and appropriately adjusting the depth of neuromuscular blockade. The choice of one or several of these options is determined by the estimated remaining duration of surgery, the anesthetic technique, and the surgical maneuver required. Importantly, the single best (and only) method to ensure appropriate dosing and timing of additional NMBD is assessment of the depth of neuromuscular block by objective (quantitative) means.[118c]

It is important to keep these options in mind to avoid relying on only neuromuscular blockade to achieve a desired degree of surgical relaxation.

Varying Sensitivities of Different Muscle Groups

The sensitivity of the neuromuscular junctions to the effects of neuromuscular relaxants among various muscle groups varies greatly. Paton and Zaimis[118d] demonstrated in 1951 that some of the muscles of respiration, such as the diaphragm, were more resistant to curare than others. The dose of nondepolarizing NMBDs needed to block the diaphragm is 1.5 to 2 times that of the adductor pollicis. Thus complete paralysis of the diaphragm is not expected with doses of NMBDs used to block neuromuscular transmission at the adductor pollicis.[119] Similarly, the laryngeal adductor muscles are more resistant to nondepolarizing NMBDs than the more peripheral muscles such as the adductor pollicis,[120] at which all dosing recommendations for NMBDs and their antagonists have been made. The sparing effect of NMBDs on the laryngeal adductor muscles has been documented with vecuronium, rocuronium, cisatracurium, and mivacurium.[120-122] Plaud and colleagues studied the pharmacokinetic-pharmacodynamic relationship of NMBDs at the adductor pollicis and the laryngeal adductors.[123] These investigators found that the concentration in the effect compartment producing 50% of the maximum block was significantly greater at the laryngeal adductor muscles (1.5 μg/mL) than that at the adductor pollicis muscle (0.8 μg/mL). Convincing evidence indicates that the EC_{50} for almost all drugs is 50% to 100% higher at the diaphragm or larynx than it is at the adductor pollicis. These differences may be caused by any of several factors. Waud and Waud found that following curare administration, neuromuscular transmission occurs when approximately 18% of the receptors are free at the diaphragm, whereas it does not occur at the peripheral muscles unless 29% of receptors are free.[124] The reason may be higher receptor density, greater release of acetylcholine, or less acetylcholinesterase activity. The lower density of acetylcholine receptors in slow muscle fibers, such as found in the peripheral muscles, explains, in part, the lower margin of safety for neuromuscular transmission when compared with that in the faster muscle fibers in the laryngeal adductors. Muscle sensitivity to succinylcholine is different from that of other NMBDs. Succinylcholine is the only muscle relaxant that, at equipotent doses, causes greater neuromuscular block at the vocal cords than at the adductor pollicis. Some data suggest that in contrast to nondepolarizing NMBDs, succinylcholine is more effective in blocking the muscles composed of primarily fast-contracting fibers.[125]

In spite of the relative resistance to NMBDs, the onset of neuromuscular block is significantly faster at the diaphragm and the laryngeal adductors than at the adductor pollicis. Fisher and associates postulated that more rapid equilibration (shorter effect site equilibration half-life [$t_{½}k_{e0}$]) of the NMBD between plasma[126] and the effect compartment at these more centrally located muscles was the explanation for this observation. The accelerated rate of equilibrium probably represents little more than differences in regional blood flow. Therefore muscle blood flow (i.e., the rate of drug delivery to the tissue), rather than a drug's intrinsic potency, may be more important in determining the onset and offset time of nondepolarizing NMBDs. Greater blood flow per gram of muscle at the diaphragm or larynx results in delivery of a higher peak plasma concentration of drug in the brief period of time

*The potentiation of nondepolarizing relaxants by different anesthetic vapors has been reported to vary from 20% to 50%. More recent data suggest, however, that this variation may be much less, particularly in the case of the intermediate- and short-acting relaxants. Therefore for the sake of simplicity, this table assumes a potentiation of 40% in the case of all volatile anesthetics.

Suggested dosages provide good intubating conditions under light anesthesia. Satisfactory abdominal relaxation may be achieved at dosages listed after intubation without a relaxant or with succinylcholine. This table is intended as a general guide to dosage. Individual relaxant requirement should be confirmed with a neuromuscular monitor.

ED_{95}, Dose causing on average 95% suppression of neuromuscular response; *N_2O*, nitrous oxide; *O_2*, oxygen.

before rapid redistribution occurs. Plaud and colleagues confirmed this hypothesis by demonstrating a faster transfer rate constant (i.e., $t_{1/2}k_{e0}$) at the laryngeal adductors (2.7 minutes) than at the adductor pollicis (4.4 minutes).[123] Greater resistance to neuromuscular blockade accounts for the faster recovery of the respiratory muscles and the muscles of the abdominal wall than at the adductor pollicis muscle. Recovery occurs more rapidly because blood concentration of the NMBD must decrease more in the muscles of respiration than in the adductor pollicis for recovery of neuromuscular function to begin.

In contrast, the muscles of the upper airway are particularly sensitive to the effects of muscle relaxants. The masseter is 15% more sensitive to nondepolarizing NMBDs than is the adductor pollicis.[127] Significant weakness of the muscles of the upper airway may exist even when strength at the adductor pollicis has recovered almost to baseline values. A TOF ratio less than 0.9 at the adductor pollicis (with a calibrated neuromuscular monitor) is associated with impaired pharyngeal function, reduced resting tone in the upper esophageal sphincter muscle, and decreased coordination of the muscles involved in swallowing, all of which cause an increased incidence of misdirected swallows, or aspiration.[128] Because of the resistance of the diaphragm and laryngeal muscles to neuromuscular block, patients may be weak in pharyngeal muscle groups while being able to breathe as long as an endotracheal tube is in place. Once the trachea is extubated, however, patients may not be able to maintain a patent airway or protect their airway.[129] This is likely the reason that patients with a TOF less than 0.9 in the postanesthesia care unit (PACU) are more likely to develop critical respiratory events than those whose TOF ratio is 0.9 or greater.[129a] Some investigators[129b] have demonstrated that among patients who received NMBD, those who did not receive reversal were more than twice as likely to develop pneumonia after surgery.

The increase in ventilation during hypoxia is mainly governed by afferent neuronal input from peripheral chemoreceptors of the carotid body. Acetylcholine is involved in the transmission of afferent neuronal activity from the carotid body to the central nervous system (CNS). Eriksson and associates have shown that partial neuromuscular block (TOF ratio of 0.7) reduces specifically the ventilatory responses to isocapnic hypoxia without altering the response to hypercapnia. The ventilatory response to hypoxia returns to control values after recovery of a TOF ratio to above 0.9.[129c] The mechanism behind this interaction seems to be a spontaneous, reversible depression of carotid body chemoreceptor activity during hypoxia.[129d]

DOSAGE

General Dosage Guidelines

Proper selection of the dose of nondepolarizing NMBD and quantitative monitoring are required to ensure that the desired effect is achieved without overdose of the relaxant (Tables 27.4 and 27.5).

TABLE 27.5 Pharmacodynamic Effects of Succinylcholine and Nondepolarizing Neuromuscular Blockers

*Time from injection of the intubating dose to recovery of twitch to 25% of control.

†For atracurium and mivacurium, slower injection (30 seconds) is recommended to minimize circulatory effects.

ED_{95}, Dose causing on average 95% suppression of neuromuscular response.

The intensity of maximum blockade is directly affected by dose. If a small dose of NMBD is administered, neuromuscular block may not occur because the amount administered is inadequate to overcome the margin of safety at the neuromuscular junction. When doses lower than those required to cause 100% neuromuscular blockade are administered, the time required to reach maximum effect is a function of the NMBD and blood flow to the muscles. It is independent of the dose administered. However, if the administered dose is high enough to cause 100% neuromuscular blockade, the time required for maximum block will depend on the dose of NMBD administered. Larger doses will, up to a certain point, produce a faster onset of effect.[130] Increasing the dose of NMBD beyond that point will not further decrease the time to onset of maximal effect, and may significantly prolong the total duration of neuromuscular blockade, contributing to residual postoperative paralysis.

In addition to a general knowledge of the pharmacodynamics and pharmacokinetics of NMBDs and understanding of the guidelines for dosing, optimal practice requires that dosing be adjusted to account for variability in individual patients' responses to NMBDs. This adjustment cannot be made without using a quantitative (objective) monitor of neuromuscular blockade any time that an NMBD is administered to a patient. Overdosage must be avoided for several

TABLE 27.6 Suggested Definitions of the Depth of Neuromuscular Block Based on Subjective and Objective Criteria

Depth of Block	Posttetanic Count	Train-of-Four Count	Subjective Train-of-Four Ratio	Measured Train-of-Four Ratio
Intense (profound) block	0	0	0	0
Deep block	≥1	0	0	0
Moderate block	NA	1-3	0	0
Light (shallow) block	NA	4	Fade present	0.1-0.4
Minimal block (near recovery)	NA	4	No fade	>0.4 but <0.90
Full recovery (normal function)	NA	4	No fade	≥0.90-1.0

reasons: to limit the duration of drug effect so that it matches the anticipated length of surgery; to avoid unwanted cardiovascular side effects associated with large NMBD doses; and to minimize residual neuromuscular block postoperatively.

Initial and Maintenance Dosage

The initial dose of NMBD is determined by the reason for administration. Traditionally, doses used to facilitate tracheal intubation are twice the ED_{95} (see Table 27.4). If, however, the trachea has been intubated without the use of an NMBD and the purpose in administering an NMBD is to produce surgical relaxation, a dose that is slightly less than the ED_{95} (see Table 27.5) may be sufficient in most surgical settings. Administration of NMBDs solely for surgical relaxation does not prevent vocal cord injury and postoperative hoarseness caused by intubation without NMBD. Additionally, ensuring maximal neuromuscular block by using quantitative means (e.g., a TOF count of zero) rather than being guided by clinical judgment will result in less hemodynamic instability during laryngoscopy and better intubating conditions.[130a] Administering a smaller initial dose may be sufficient in the presence of any of the potent inhalational anesthetics (see the later section on drug interactions), but the dosing should always be guided by quantitative monitoring.

To avoid prolonged residual paralysis, inadequate antagonism of residual blockade, or both, the main goal in dosing NMBDs should be to use the lowest possible dose that provides adequate relaxation for surgery. Moreover, clinical management of individual patients should be guided by monitoring of the neuromuscular block, ideally with an objective neuromuscular monitoring technique, to allow safe intraoperative administration of the NMBD and its antagonism by neostigmine or sugammadex (see also Chapter 43, Neuromuscular Monitoring).

In an adequately anesthetized and monitored patient, little reason exists to abolish the TOF responses to peripheral nerve stimulation completely. However, if deep levels of block are required to maintain paralysis of the diaphragm and the abdominal wall muscles, response of the adductor pollicis to stimulation of the ulnar nerve may disappear. In this case, monitoring the depth of neuromuscular block can be accomplished using the posttetanic count (PTC) at the adductor pollicis or TOF ratio at the corrugator supercilii.[131,132] Supplemental (maintenance) doses of NMBDs should be approximately one tenth (in case of long-acting NMBDs) to one fourth (in the case of intermediate- and short-acting NMBDs) the initial dose and should not be given until quantitative evidence of beginning recovery from the previous dose is present.

Relaxation can be maintained by continuous infusion of intermediate- and short-acting drugs. This approach is useful in maintaining a stable depth of neuromuscular blockade and allows adjustment of the depth of relaxation according to surgical needs. The depth of neuromuscular blockade maintained is moderate, if possible, to ensure complete spontaneous recovery of neuromuscular function at the end of a surgical procedure or prompt antagonism of residual effects. Suggested definitions of the depth of neuromuscular block are listed in Table 27.6.[132a] Table 27.4 lists the approximate dose ranges that are typically required during infusions to maintain 90% to 95% blockade of the twitch (one twitch visible on TOF stimulation) during a nitrous oxide–oxygen anesthetic supplemented with intravenous anesthetics. Infusion dosage is usually decreased by 30% to 50% in the presence of potent volatile anesthetics.

NEUROMUSCULAR BLOCKING DRUGS AND TRACHEAL INTUBATION

Rapid onset of neuromuscular blockade is one of the requirements for securing an airway promptly. It is affected by several factors, including muscle blood flow, rate of delivery of the drug to the neuromuscular junction, receptor affinity, plasma clearance of the NMBD, and the mechanism of neuromuscular blockade (depolarizing vs. nondepolarizing)[96,116a,133](see Table 27.5 and Fig. 27.9). Onset time decreases as ED_{50} increases. When a potent NMBD is administered, fewer molecules are administered than in the case of an equipotent dose of a less potent drug. Because of this lower concentration gradient, more time is required for sufficient molecules of a potent drug to be delivered to the neuromuscular junction. Thus onset time is longer. This concept was verified by Kopman and colleagues, who demonstrated that, when giving equipotent doses of gallamine, dTc, and pancuronium, onset time was slower with the more potent pancuronium and faster with the less potent gallamine. Except for atracurium,[135] the molar potency (the ED_{50} or ED_{95} expressed as μM/kg) is highly predictive of a drug's initial rate of onset of effect (at the adductor pollicis muscle).[133] A drug's measured molar potency is the end result of many contributing factors: the drug's intrinsic potency (the CE_{50}, which is the biophase

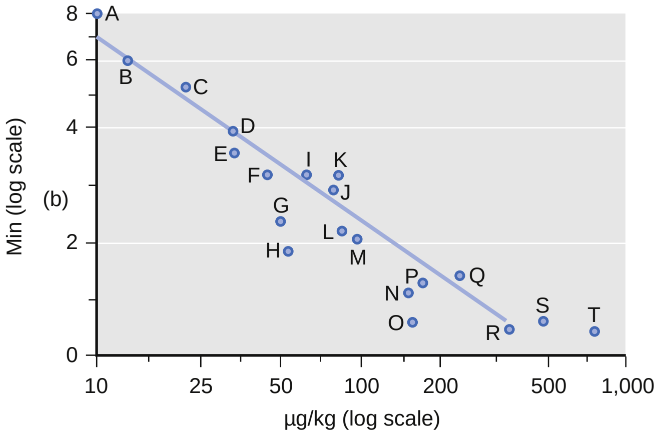

Fig. 27.9 Linear regression of onset of neuromuscular blockade (ordinate) versus potency of a series of steroidal relaxants studied in the cat model by Bowman and associates.[96] The data show that onset may be increased in compounds of low potency and encouraged the eventual development of rocuronium and rapacuronium (ORG 9487). *A,* Pipecuronium; *B,* ORG 8788; *C,* pancuronium; *D,* vecuronium; *E-M* and *O-T,* ORG 9274, 9360, 9273, 8715, 6502, 9216, 7931, 8730, 7617, 9275, 6368, 8764, 9382, and 7684 (respectively); *N,* RGH-4201. Onset and recovery from blockade occur more rapidly in the larynx. *T1,* First twitch of train-of-four. (From Donati F, Meistelman C, Plaud B. Vecuronium neuromuscular blockade at the adductor muscles of the larynx and adductor pollicis. *Anesthesiology.* 1991;74:833–837.)

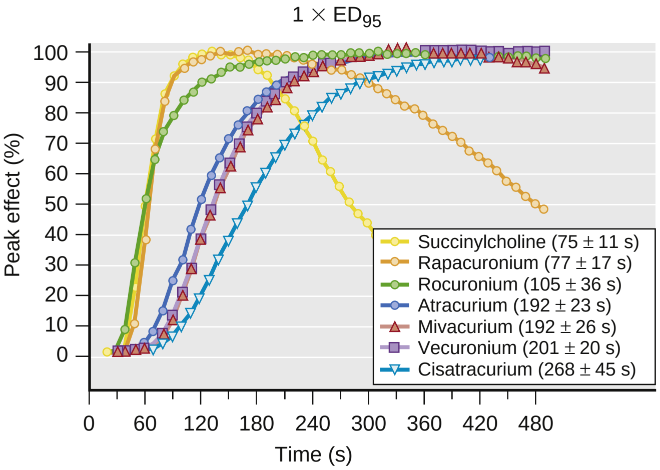

Fig. 27.10 Percentages of peak effect after a dose causing on average 95% suppression of neuromuscular response *(ED_{95})* of succinylcholine, rocuronium, rapacuronium, vecuronium, atracurium, mivacurium, and cisatracurium at the adductor pollicis muscle. Times (mean ± standard deviation) in seconds to 95% of peak effect are shown in parentheses. (Data from references 114, 133, and 135.)

concentration resulting in 50% twitch depression), the rate of equilibration between plasma and biophase (k_{e0}), the initial rate of plasma clearance, and probably other factors as well.[136] Notably, rocuronium has a molar potency (ED_{95}) of 0.54 μM/kg, which is approximately 13% that of vecuronium and only 9% that of cisatracurium; this finding illustrates the expected faster onset of rocuronium at the adductor pollicis muscle, as opposed to vecuronium and cisatracurium. Donati and Meistelman proposed a model to explain this inverse potency–onset relationship.[116a]

The times to 95% blockade at the adductor pollicis after administration of the ED_{95} dose of succinylcholine, rocuronium, vecuronium, atracurium, mivacurium, and cisatracurium are shown in Fig. 27.10.[114,133,135] The illustration shows that the most potent compound, cisatracurium, has the slowest onset, and the least potent compound, rocuronium, has the most rapid onset.[114,133,135] Bevan also proposed that rapid plasma clearance is associated with a rapid onset of action.[137] The fast onset of succinylcholine's action is related to its rapid metabolism and plasma clearance.

The onset of neuromuscular blockade is much faster in the muscles that are relevant to obtaining optimal intubating conditions (laryngeal adductors, diaphragm, and masseter) than in the muscle that is typically monitored (adductor pollicis) (Fig. 27.11).[121] Thus neuromuscular blockade develops faster, has a shorter maximum depth and duration of effect, and recovers more quickly in these central muscles (Table 27.7).[120-122,138,139]

Paralysis following intravenous administration does not occur instantaneously even with large doses of muscle relaxants. Onset of blockade occurs 1 to 2 minutes earlier in the laryngeal muscles than at the adductor pollicis after administration of nondepolarizing NMBDs. The pattern of blockade (onset, depth, and speed of recovery) in the corrugator supercilii muscle is similar to that in the larynx,[119] the diaphragm, and the muscles of the abdominal wall. By monitoring the onset of neuromuscular blockade at the corrugator supercilii, one can predict the quality of tracheal intubating conditions. Good to excellent intubating conditions are observed in more than 90% of patients after disappearance of the TOF responses (a TOF count of zero) at the corrugator supercilii.[131] The onset of maximal blockade in the larynx also corresponds with the point at which the adductor pollicis muscle begins to show palpable evidence of weakening.

Rapid Tracheal Intubation

Rocuronium in high dose (0.9-1.2 mg/kg) or succinylcholine 1.5 mg/kg can be used interchangeably for rapid tracheal intubation because they provide adequate intubating conditions within 60 to 90 seconds. Hence if succinylcholine is considered undesirable or contraindicated, high doses of rocuronium can be administered.[140] The onset of action of other nondepolarizing NMBDs can be accelerated by administering a priming dose of the NMBD[141] or

Clinical duration is the time until the first twitch of train-of-four (T1) has recovered to 25% of its control value. Mean and standard deviation[122,138,139] or standard error of the mean.[120,121]

by using combinations of NMBDs.[142] Although combinations of mivacurium and rocuronium can achieve rapid onset without undue prolongation of action and without undesirable side effects,[142] combinations of compounds of different structures may result in a marked prolongation of neuromuscular blockade. Additionally, combining different NMBDs may not consistently result in a rapid onset of neuromuscular block.

Timing Technique. This technique entails administration of a single intubating dose (two times the ED_{95}) of a rapid-onset NMBD such as rocuronium to an awake patient, followed by the administration of the anesthetic induction agent at the onset of clinical signs of weakness such as ptosis or loss of ability to maintain the raised arm. Using this technique, 0.6 mg/kg rocuronium can provide good to excellent intubating conditions within 45 seconds after induction of anesthesia.[142a] Because of the potential for unpleasant symptoms and recall associated with neuromuscular paralysis in awake patients, this technique is no longer used clinically.

Priming Technique. Since the introduction of rocuronium into clinical practice, the use of priming technique has almost disappeared. When priming, a small, subparalyzing dose of the nondepolarizer (≈20% of the ED_{95} or ≈10% of the intubating dose) is administered 2 to 4 minutes before the intubating dose of the compound.[141] This procedure accelerates the onset of blockade for most nondepolarizing NMBDs only by 30 to 60 seconds, thereby indicating that intubation can be performed within 90 seconds of the second dose. However, the intubating conditions that occur after priming are only marginally improved and do not match those that occur after succinylcholine. The size of the priming dose is limited by its effects on the awake patient, since the anesthetic induction agent is administered only immediately prior to the intubating dose of NMBD. Further, priming doses can cause subtle degrees of neuromuscular blockade and increase the patient's discomfort, the risks of aspiration, and difficulty swallowing and breathing.[143] This technique is contraindicated in patients with abnormal airway anatomy or increased sensitivity to NMBDs such as patients with myasthenia gravis or those taking magnesium.

Large-Dose Regimen for Rapid Tracheal Intubation. Large doses of NMBDs are usually recommended when intubation must be accomplished in less than 90 seconds. High-dose regimens are associated with considerably prolonged duration of action and potentially increased cardiovascular side effects, however (see Table 27.5).[140,144] Increasing the dosage of rocuronium from 0.6 mg/kg (twice the ED_{95}) to 1.2 mg/kg (four times the ED_{95}) shortens the onset time of complete neuromuscular block from 89 to 55 seconds but essentially doubles the clinical duration of action of the compound (the recovery of the first twitch of TOF [T1] to 25% of baseline values) from 37 to 73 minutes.[140]

Small-Dose Relaxants for Tracheal Intubation. Small doses of NMBDs can be used for routine tracheal intubation. The use of smaller doses of NMBDs has the following two possible advantages: (1) it shortens the time to recovery from neuromuscular blockade, and (2) it reduces the requirement for anticholinesterase drugs. Rocuronium has the shortest onset time of all the nondepolarizing NMBDs currently available.[121,122] The maximal effect of either 0.25 or 0.5 mg/kg of rocuronium at the laryngeal muscles occurs after 1.5 minutes.[121] This interval is shorter than the 3.3 minutes reported after administration of equipotent

	Muscle X	Adductor pollicis
EC_{50} (µg/mL)	3.00	1.18
$t_{1/2}k_{e0}$ (min)	1.93	3.85
Hill coefficient	4.00	4.50

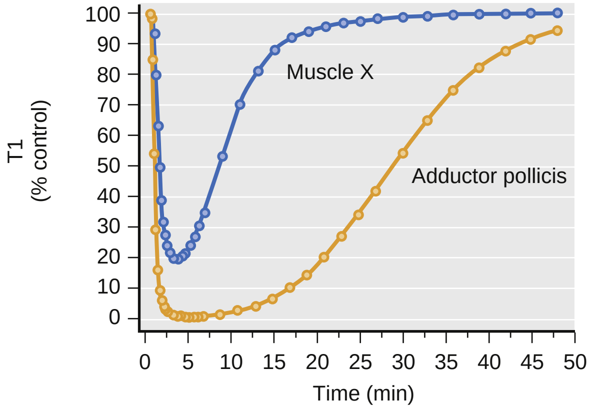

Fig. 27.12 A computer simulation based on Sheiner's model[115] and data reported by Wierda and colleagues. The dose causing on average 95% suppression of neuromuscular response (ED_{95}) of rocuronium at the adductor pollicis from this model is 0.33 mg/kg. Rocuronium, 0.45 mg/kg is given as a bolus at time zero. Muscle X represents a muscle (e.g., the diaphragm or the laryngeal adductors) that is less sensitive to the effects of nondepolarizing relaxants than the adductor pollicis but has greater blood flow. In this example, the concentration of rocuronium producing 50% block (EC_{50}) of muscle X is 2.5 times that of the adductor pollicis, but the half-life of transport between the plasma and effect compartment ($t_{1/2}k_{e0}$) of muscle X is only half as long. The rapid equilibration between plasma concentrations of rocuronium and muscle X results in the more rapid onset of blockade of muscle X than of the adductor pollicis. The greater EC_{50} at muscle X explains the faster recovery of this muscle than of the adductor pollicis from neuromuscular blockade. Lower blood concentrations of rocuronium must be achieved at the adductor pollicis than at muscle X before recovery begins. *T1,* First twitch of train-of-four. (From Naguib M, Kopman AF. Low dose rocuronium for tracheal intubation. *Middle East J Anesthesiol.* 2003;17:193–204, with permission from the *Middle East Journal of Anesthesiology.*)

doses of vecuronium (0.04 or 0.07 mg/kg),[120] and it is only slightly longer than the 0.9 minutes reported after 0.25 or 0.5 mg/kg of succinylcholine (see Table 27.7).[125]

With a better understanding of the multiple factors that contribute to satisfactory conditions for intubation, it is now possible to administer NMBDs thoughtfully in this fashion. Intubating conditions are related more closely to the degree of neuromuscular blockade of the laryngeal adductor muscles than to the degree of blockade typically monitored at the adductor pollicis. Fig. 27.12 demonstrates this principle.[136] In the presence of an adequate depth of anesthesia, complete blockade at the larynx or diaphragm, or both, may not be a prerequisite for satisfactory intubating conditions. Kopman and colleagues noted that 0.5 mg/kg of rocuronium (1.5 times the ED_{95}) provided satisfactory conditions for intubation in patients anesthetized with 12.5 µg/kg of alfentanil and 2.0 mg/kg of propofol if laryngoscopy was delayed for 75 seconds after drug administration.[145] It was furthermore estimated that 1.5 times the ED_{95} of rocuronium would produce at least 95% blockade in 98% of the population.[145] A similar or lower multiple of rocuronium's ED_{95} was shown to have a faster onset and shorter duration of action than those of atracurium[146] or cisatracurium.[109] In most patients receiving 15 µg/kg of alfentanil followed by 2.0 mg/kg of propofol and 0.45 mg/kg of rocuronium, good to excellent conditions for intubation are present 75 to 90 seconds after the completion of drug administration.

METABOLISM AND ELIMINATION

The specific pathways of the metabolism (biotransformation) and elimination of NMBDs are summarized in Table 27.8. Of the nondepolarizing NMBDs listed, pancuronium, pipecuronium, vecuronium, atracurium, cisatracurium, and mivacurium are the only drugs that are metabolized or degraded. Nearly all nondepolarizing NMBD molecules contain ester linkages, acetyl ester groups, and hydroxy or methoxy groups. These substitutions, especially the quaternary nitrogen groups, confer a high degree of water solubility with only slight lipid solubility. The hydrophilic nature of relaxant molecules enables easy elimination in the urine through glomerular filtration, with no tubular resorption or secretion. Therefore all nondepolarizing NMBDs show elimination of the parent molecule in the urine as the basic route of elimination; those with a long duration of action thus have a clearance rate that is limited by the glomerular filtration rate (1-2 mL/kg/min).

Steroidal Compounds

Long-Acting Neuromuscular Blocking Drugs. Pancuronium is cleared largely by the kidney[147] and, to a limited extent, by hepatic uptake and elimination. A small amount (15%-20%) is deacetylated at the 3 position in the liver, but this makes a minimal contribution to the total clearance. Deacetylation also occurs at the 17 position, but to such a small extent as to be clinically irrelevant. The three known metabolites have been individually studied in anesthetized humans.[148] The 3-OH metabolite is the most potent of the three, being approximately half as potent as pancuronium, and is the only one present in detectable concentrations in the plasma. This metabolite has pharmacokinetics and duration of action similar to those of pancuronium.[148] The 3-OH metabolite is most likely excreted largely by the kidney.[148] The parent compound and the 3-OH metabolite are also cleared in small amounts through a minor liver pathway. The total clearance is delayed, and the duration of action is significantly lengthened, by severe disorders of renal or hepatic function.[149-151]

Intermediate-Acting Neuromuscular Blockers. Vecuronium, the 2-desmethyl derivative of pancuronium, is more lipid soluble than pancuronium because of the absence of the quaternizing methyl group at the 2 position. It undergoes two to three times more metabolism than pancuronium. Vecuronium is taken up into the liver by a carrier-mediated transport system,[152] and it is then deacetylated at the 3 position by liver microsomes. Approximately 12% of vecuronium clearance is through conversion to 3-desacetylvecuronium,[153] and 30% to 40% of the drug is cleared in the bile as the parent compound.[154] Although the liver is the principal organ of elimination for vecuronium, the drug also undergoes significant (up to 25%) renal excretion, and this combined organ elimination gives it a clearance rate of 3 to 6 mL/kg/min.[153,155]

			ELIMINATION		
Drug	**Duration**	**Metabolism (%)**	**Kidney (%)**	**Liver (%)**	**Metabolites**
Succinylcholine	Ultrashort	Butyrylcholinesterase (98%-99%)	<2%	None	Monoester (succinyl monocholine) and choline; the monoester is metabolized much more slowly than succinylcholine
Gantacurium	Ultrashort	Cysteine (fast) and ester hydrolysis (slow)	?	?	Inactive cysteine adduction product, chloroformate monoester, and alcohol
Mivacurium	Short	Butyrylcholinesterase (95%-99%)	<5%	None	Monoester and quaternary alcohol; the metabolites are inactive and most likely are not metabolized any further
			(Metabolites eliminated in urine and bile)		
Atracurium	Intermediate	Hofmann elimination and nonspecific ester hydrolysis (60%-90%)	10%-40%	None	Laudanosine, acrylates, alcohols, and acids; although laudanosine has CNS-stimulating properties, the clinical relevance of this effect is negligible
			(Metabolites eliminated in urine and bile)		
Cisatracurium	Intermediate	Hofmann elimination (77%?)	Renal clearance is 16% of total		Laudanosine and acrylates; ester hydrolysis of the quaternary monoacrylate occurs secondarily; because of the greater potency of cisatracurium, laudanosine quantities produced by Hofmann elimination are 5-10 times lower than in the case of atracurium, thus making this a nonissue in practice
Vecuronium	Intermediate	Liver (30%-40%)	40%-50%	50%-60% ≈60%	The 3-OH metabolite accumulates, particularly in renal failure; it has ≈80% the potency of vecuronium and may be responsible for delayed recovery in ICU patients
			(Metabolites excreted in urine and bile) ≈40%		
Rocuronium	Intermediate	None	10%-25%	>70%	None
Pancuronium	Long	Liver (10%-20%)	85%	15%	The 3-OH metabolite may accumulate, particularly in renal failure; it is approximately two thirds as potent as the parent compound
d-Tubocurarine	Long	None	80% (?)	20%	None

3-OH, 3-hydroxy; *?,* unknown; *CNS,* central nervous system; *ICU,* intensive care unit.

The principal metabolite of vecuronium, 3-desacetylvecuronium, is a potent NMBD (≈80% of the potency of vecuronium). The metabolite, however, has slower plasma clearance and longer duration of action than vecuronium.[153] 3-Desacetylvecuronium has a clearance rate of 3.5 mL/kg/min, and renal clearance accounts for approximately one sixth of its elimination.[153] In patients with renal failure in the ICU, 3-desacetylvecuronium can accumulate and produce prolonged neuromuscular blockade.[156] Other putative metabolites are 17-desacetylvecuronium and 3,17-bisdesacetylvecuronium, neither of which occurs in clinically significant amounts.

Rocuronium is eliminated primarily by the liver, with a small fraction (≈10%) eliminated in the urine.[157] It is taken up into the liver by a carrier-mediated active transport system.[158] The putative metabolite, 17-desacetylrocuronium, has low (5%-10%) neuromuscular blocking activity of the parent drug and it has not been detected in significant quantities. The elimination of rocuronium occurs predominately through its biliary excretion. The organic anion transporting peptide 1A2 (OATP1A2) mediates the hepatocellular uptake of a variety of drugs, including rocuronium. The peptide is encoded by the *SLCO1A2* gene and is expressed in the bile duct cells (cholangiocytes) of the liver.[158a] Genetic polymorphism of the *SLCO1A2* gene has recently been reported, and was shown to reduce the clearance of rocuronium in patients undergoing elective surgeries.[158a] This reduction in the biliary excretion may partially explain the marked prolongation in the duration of action of rocuronium in some patients.[158b]

Benzylisoquinolinium Compounds

Short-Acting Neuromuscular Blocking Drugs. Mivacurium is hydrolyzed in the plasma by butyrylcholinesterase to a monoester and an amino alcohol,[9] which are excreted in urine and bile. They have less than 1% of the neuromuscular blocking activity of the parent compound. Less than 5% of mivacurium is excreted in the urine as the parent compound.

Mivacurium consists of three stereoisomers, and the clearances of the two most pharmacologically active isomers, the *cis-trans* and *trans-trans*, are approximately 100 and 50 to 70 mL/kg/min, respectively.[94,159,160] These two isomers show elimination half-lives of 2 to 3 minutes.[94] The third stereoisomer, the *cis-cis*, is present as only 4% to 8% of the mivacurium mixture and has less than 10% of the neuromuscular blocking potency of the other two isomers.[94] Consequently, even though it has a much longer elimination half-life (55 minutes) and lower clearance (≈4 mL/kg/min) than the two other isomers, it does not contribute significantly to the duration of action of mivacurium.[94] This rapid enzymatic clearance of mivacurium accounts for its short duration of action.[9,94] When butyrylcholinesterase activity is significantly decreased, however, as in the rare patient who is homozygous for genetically atypical enzymes, the duration of action of mivacurium is prolonged for up to several hours.[161-164]

CW 1759-50 is an ultrashort-acting nondepolarizing NMBD that was developed to minimize the histaminoid side effects associated with gantacurium. In laboratory animals, the ED_{95} of CW 1759-50 is 0.03 mg/kg (cat) and 0.069 mg/kg (rhesus monkey). Its total duration of action (spontaneous recovery) is approximately 8 minutes, and it is minimally prolonged (12 minutes) after administration of doses four times its ED_{95}.[11a,11b] It can be antagonized rapidly (2 minutes) by L-cysteine. Its development for clinical use is undergoing.

Intermediate-Acting Neuromuscular Blocking Drugs. Atracurium is metabolized through two pathways: Hofmann elimination and nonspecific ester hydrolysis. Hofmann elimination is a purely chemical process that results in loss of the positive charges by molecular fragmentation to laudanosine (a tertiary amine) and a monoquaternary acrylate, compounds that are thought to have no neuromuscular and little or no cardiovascular activity of clinical relevance.[165]

Because it undergoes Hofmann elimination, atracurium is relatively stable at pH 3.0 and 4°C and becomes unstable when it is injected into the bloodstream. Early observations of the breakdown of the drug in buffer and plasma showed faster degradation in plasma, a finding suggesting a possible enzymatic hydrolysis of the ester groups. Further evidence suggested that ester hydrolysis may be more important than originally realized in the breakdown of atracurium.[166] By using a pharmacokinetics analysis, Fisher and associates concluded that a significant amount of clearance of atracurium may be by routes other than ester hydrolysis and Hofmann elimination.[167] Thus it appears that atracurium's metabolism is complicated and may not be completely understood.[167]

Laudanosine, a metabolite of atracurium, has CNS-stimulating properties. Because it crosses the blood-brain barrier, laudanosine was thought to cause excitement and seizure activity. However, plasma concentrations of this metabolite are very low, and adverse effects are unlikely to occur with atracurium (or cisatracurium) use in either the operating room or the ICU.

Atracurium is a mixture of 10 optical isomers. Cisatracurium is the 1R *cis*–1′R *cis* isomer of atracurium.[90] Like atracurium, cisatracurium is metabolized by Hofmann elimination to laudanosine and a monoquaternary acrylate.[168,169] In contrast, however, no ester hydrolysis of the parent molecule occurs. Hofmann elimination accounts for 77% of the total clearance of 5 to 6 mL/kg/min. Twenty-three percent of the drug is cleared through organ-dependent means, and renal elimination accounts for 16% of this.[169] Because cisatracurium is approximately four or five times as potent as atracurium, approximately five times less laudanosine is produced, and, as with atracurium, accumulation of this metabolite is not thought to be of any consequence in clinical practice.

Long-Acting Neuromuscular Blocking Drugs. dTc has no active metabolism and the kidney is the major pathway of elimination, with approximately 50% of a dose eliminated through renal pathways. The liver is likely a secondary route of elimination.

Asymmetric Mixed-Onium Fumarates

Gantacurium and CW 002 are degraded by two chemical mechanisms, neither of which is enzymatic: (1) rapid formation of an apparently inactive cysteine adduction product and (2) slower hydrolysis of the ester

bond to presumably inactive hydrolysis products (see Fig. 27.7).[11,170] CW 1759-50 is degraded nonenzymatically by endogenous L-cysteine at physiological pH and temperature, which accounts for its ultrashort duration of action.

In summary, the only short-acting nondepolarizing NMBD, mivacurium, is cleared rapidly and almost exclusively by metabolism by butyrylcholinesterase, thus resulting in much greater plasma clearance than that of any other nondepolarizing NMBD.[9] NMBDs of intermediate duration, such as vecuronium, rocuronium, atracurium, and cisatracurium, have clearance rates in the range of 3 to 6 mL/kg/min because of multiple pathways of degradation, metabolism, and/or elimination. Atracurium is cleared two to three times more rapidly than the long-acting drugs.[171-174] Similar clearance values have been obtained for rocuronium[175-179] and cisatracurium.[168,169,180] The long-acting NMBDs undergo minimal or no metabolism, and they are eliminated largely unchanged, mostly by renal excretion. Hepatic pathways are less important in their metabolism.

ADVERSE EFFECTS OF NEUROMUSCULAR BLOCKING DRUGS

NMBDs seem to play a prominent role in the incidence of adverse reactions that occur during anesthesia. The Committee on Safety of Medicines in the United Kingdom reported that 10.8% (218 of 2014) of adverse drug reactions and 7.3% of deaths (21 of 286) were attributable to the NMBDs.[181]

Autonomic Effects

While NMBDs have little penetration through the blood-brain barrier, they may interact with nicotinic and muscarinic cholinergic receptors within the peripheral nervous system, in particular the sympathetic and parasympathetic nervous systems and at the nicotinic receptors of the neuromuscular junction.

Dose-response ratios comparing the neuromuscular blocking potencies of these drugs (the ED_{95}) with their potencies in blocking vagal (parasympathetic) or sympathetic ganglionic transmission (the ED_{50}) can be constructed (Table 27.9). These ratios are termed the autonomic margin of safety of the relaxant in question. The higher the dose ratio, the lower is the likelihood of, or the greater the safety ratio for, the occurrence of the particular autonomic effect. The side effect is considered absent (none) in clinical practice if the safety ratio is greater than 5; it is weak or slight if the safety ratio is 3 or 4, moderate if 2 or 3, and strong or prominent if the ratio is 1 or less.

These autonomic responses are not reduced by slower injection of the muscle relaxant. They are dose related and additive over time if divided doses are given. If identical to the original dose, subsequent doses will produce a similar response (i.e., no tachyphylaxis will occur). This is not the case, however, when the side effect of histamine release is in question. Cardiovascular responses secondary to histamine release are decreased by slowing the injection rate, and the response undergoes rapid tachyphylaxis. The autonomic effects of NMBDs are summarized in Table 27.10.

Histamine Release. Quaternary ammonium compounds (e.g., NMBDs) are generally weaker histamine-releasing substances than are tertiary amines such as morphine. Nevertheless, when large doses of certain NMBDs are administered rapidly, erythema of the face, neck, and upper torso may develop, as well as a brief decrease in arterial pressure and a slight to moderate increase in heart rate. Bronchospasm in this setting is very rare. The clinical effects of histamine are seen when plasma concentrations increase 200% to 300% of baseline values, and these effects involve chemical displacement of the contents of mast cell granules containing histamine, prostaglandin, and possibly other vasoactive substances.[182] The serosal mast cell, located in the skin and connective tissue and near blood vessels and nerves, is principally involved in the degranulation process.[182]

The side effect of histamine release is most often noted following administration of the benzylisoquinolinium class of muscle relaxants, although it has also been noted in steroidal relaxants of low potency. The effect is usually of short duration (1-5 minutes), is dose related, and is

TABLE 27.10 Clinical Autonomic Effects of Neuromuscular Blocking Drugs

clinically insignificant in healthy patients. The hypotensive cardiovascular response to 0.6 mg/kg of dTc in humans is prevented both by antihistamines and by nonsteroidal anti-inflammatory drugs (e.g., aspirin).[183] The final step in dTc-induced hypotension is modulated by prostaglandins that are vasodilators.[183] This side effect can be reduced considerably by using a slower injection rate that results in lower peak plasma concentrations of dTc. It is also prevented by prophylaxis with combinations of histamine$_1$ and histamine$_2$ blockers.[184] If a minor degree of histamine release such as described earlier occurs after an initial dose of an NMBD, subsequent doses will generally cause no response at all, as long as they are no larger than the original dose. This is clinical evidence of tachyphylaxis, an important characteristic of histamine release. A much more significant degree of histamine release occurs during anaphylactoid or anaphylactic reactions, but these are very rare.

Clinical Cardiovascular Manifestations of Autonomic Mechanisms

Hypotension. The hypotension seen with the use of atracurium and mivacurium results from histamine release, whereas dTc causes hypotension by histamine release and ganglionic blockade.[185,186] The effects of dTc occur closer to the dose required to achieve neuromuscular blockade.[113] The safety margin for histamine release is approximately three times greater for atracurium and mivacurium than it is for dTc.[182,183,186] Rapid administration of atracurium in doses greater than 0.4 mg/kg and of mivacurium in doses greater than 0.15 mg/kg has been associated with transient hypotension secondary to histamine release (Fig. 27.13).

Tachycardia. Pancuronium causes a moderate increase in heart rate and, to a lesser extent, in cardiac output, with little or no change in systemic vascular resistance.[187] Pancuronium-induced tachycardia has been attributed to the following: (1) vagolytic action,[187] probably from inhibition of M$_2$ receptors; and (2) sympathetic stimulation that involves both direct (blockade of neuronal uptake of norepinephrine) and indirect (release of norepinephrine from adrenergic nerve endings) mechanisms.[188] In humans a decrease in plasma norepinephrine levels was surprisingly found after administration of either pancuronium or atropine.[189] The investigators postulated that the increase in heart rate or rate-pressure product occurs because pancuronium (or atropine) acts through baroreceptors to reduce sympathetic outflow.[189] More specifically, the vagolytic effect of pancuronium increases heart rate and hence blood pressure and cardiac output, in turn influencing the baroreceptors to decrease sympathetic tone. Support for this concept is provided by the finding that prior administration of atropine attenuates or eliminates the cardiovascular effects of pancuronium.[187] However, a positive chronotropic effect that places emphasis on the vagolytic mechanism has not been found in humans.[190] The tachycardia seen with benzylisoquinolinium compounds is the result of histamine release.

Dysrhythmias. Succinylcholine and dTc actually reduce the incidence of epinephrine-induced dysrhythmias.[191] Possibly because of enhanced atrioventricular conduction,[192] the incidence of dysrhythmias caused by pancuronium appears to increase during halothane anesthesia.[187] There are reports of rapid tachycardia (>150 beats/min) that progressed to atrioventricular dissociation in two patients anesthetized with halothane who also received pancuronium.[193] The only other factor common to those two patients was that both were taking tricyclic antidepressant drugs.

Bradycardia. Several case reports described the occurrence of severe bradycardia and even asystole after vecuronium or atracurium administration.[194,195] All these cases were also associated with opioid coadministration. Subsequent studies indicated that administration of vecuronium or atracurium alone does not cause bradycardia.[196] When combined with other drugs that do cause bradycardia (e.g., fentanyl), however, the nonvagolytic relaxants such as vecuronium, cisatracurium, and atracurium allow this mechanism to occur unopposed. Thus the moderate vagolytic effect of pancuronium is often used to counteract opioid-induced bradycardia.

Respiratory Effects. The muscarinic cholinergic system plays an important role in regulating airway function. Five muscarinic receptors have been cloned,[197] three of which (M$_1$ to M$_3$) exist in the airways.[198] M$_1$ receptors are under

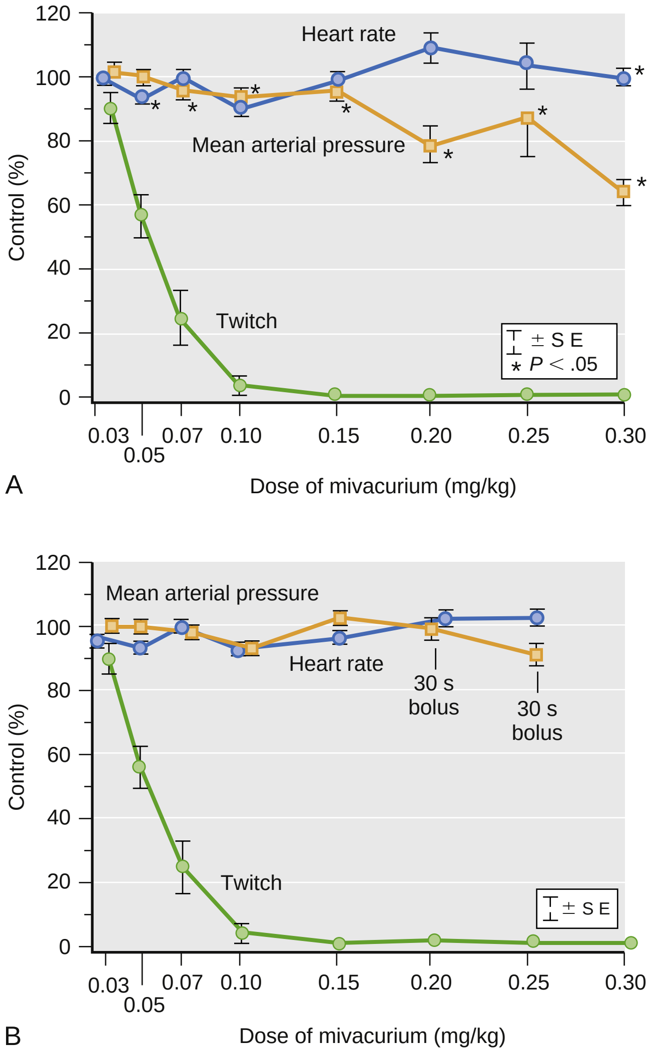

Fig. 27.13 Dose response to mivacurium in patients under nitrous oxide–oxygen-opioid anesthesia. Maximum changes at each dose are shown; *n* = 9 subjects per group. (A) With fast injection, a 15% to 20% decrease in arterial pressure occurred at 2.5 to 3 times the ED$_{95}$ (0.20-0.25 mg/kg). (B) The changes were less than 10% when slower injection (30 seconds) was done. (From Savarese JJ, Ali HH, Basta SJ, et al. The cardiovascular effects of mivacurium chloride [BW B1090U] in patients receiving nitrous oxide–opiate-barbiturate anesthesia. *Anesthesiology.* 1989;70:386–394.)

sympathetic control, and they mediate bronchodilation.[199] M_2 receptors are located presynaptically (Fig. 27.14), at the postganglionic parasympathetic nerve endings, and they function in a negative-feedback mechanism to limit the release of acetylcholine. The M_3 receptors, which are located postsynaptically (see Fig. 27.14), mediate contraction of the airway smooth muscles (i.e., bronchoconstriction).[199] Nondepolarizing NMBDs have different antagonistic activities at both M_2 and M_3 receptors.[200] For example, blockade of M_3 receptors on airway smooth muscle inhibits vagally induced bronchoconstriction (i.e., causes bronchodilation), whereas blockade of M_2 receptors results in increased release of acetylcholine that acts on M_3 receptors, thus causing bronchoconstriction.

The affinity of the compound rapacuronium to block M_2 receptors is 15 times higher than its affinity to block M_3 receptors.[200] This explains the high incidence (>9%) of severe bronchospasm[201-203] reported with this drug that resulted in its withdrawal from the market. In laboratory animals (guinea pig), CW 1759-50 is reported to have five times greater safety at both M_2 and M_3 receptors than rapacuronium.[11b]

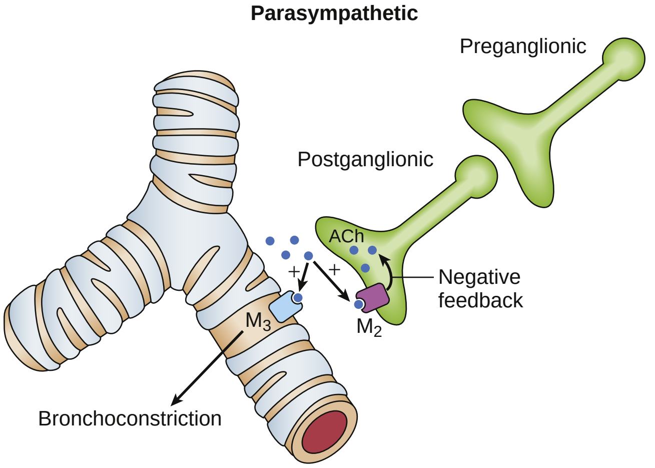

Fig. 27.14 The muscarinic *(M_3)* receptors are located postsynaptically on airway smooth muscle. Acetylcholine *(ACh)* stimulates M_3 receptors to cause contraction. *M_2* muscarinic receptors are located presynaptically at the postganglionic parasympathetic nerve endings, and they function in a negative-feedback mechanism to limit the release of ACh.

The administration of benzylisoquinolinium NMBDs (with the exception of cisatracurium) is associated with histamine release, which may result in increased airway resistance and bronchospasm in patients with hyperactive airway disease.

Allergic Reactions. The frequency of life-threatening anaphylactic (immune-mediated) or anaphylactoid reactions occurring during anesthesia has been estimated at 1 in 10,000 to 20,000 anesthetic procedures, whereas it is estimated at 1 in 6500 administrations of NMBDs in some countries.[204,205] In France, the most common causes of anaphylaxis in patients who experienced allergic reactions were reported to be NMBDs (60.6%), antibiotics (18.2%), dyes (5.4%), and latex (5.2%).[206,206a] Patients were sensitized to 2 or more NMBDS in approximately 50% of the cases and no cross-sensitivity could be predicted without skin testing. Anaphylactic reactions are mediated through immune responses involving immunoglobulin E (IgE) antibodies fixed to mast cells. Anaphylactoid reactions are not immune mediated and represent exaggerated pharmacologic responses in very rare and very sensitive individuals.

However, anaphylaxis to nondepolarizing NMBDs is not uncommon in patients without any previous exposure to any nondepolarizing NMBDs. Cross-reactivity occurs between NMBDs and food, cosmetics, disinfectants, and industrial materials.[207] Sensitization to nondepolarizing NMBDs may also be related to pholcodine, a cough-relieving medicine. Cross-reactivity is seen in 70% of patients with a history of anaphylaxis to an NMBD.[206] Six years after the withdrawal of pholcodine from the Norwegian market, the prevalence of IgE sensitization to NMBDs (succinylcholine) decreased significantly.[207a]

Steroidal compounds (e.g., rocuronium, vecuronium, or pancuronium) result in no significant histamine release.[186] For example, four times the ED$_{95}$ of rocuronium (1.2 mg/

kg) causes no significant histamine release.[208] Nevertheless, rocuronium and succinylcholine are reportedly associated with a 43.1% and 22.6% incidence, respectively, of anaphylaxis in France.[206] Rose and Fisher classified rocuronium and atracurium as having intermediate levels of risk for causing allergic reactions.[209] These investigators also noted that the increased number of reports of anaphylaxis with rocuronium is in line with the market share of that drug's usage. Watkins stated, "The much higher incidence of rocuronium reactions reported in France is currently inexplicable and is likely to remain so if investigators continue to seek a purely antibody-mediated response as an explanation of all anaphylactoid reaction presentations."[210] All nondepolarizing NMBDs may elicit anaphylaxis. More recent publications have highlighted the need for standardization of diagnostic procedures of anaphylactic reactions. Biochemical tests should be performed rapidly after occurrence of an anaphylactic reaction. An early increase in plasma histamine is observed 60 to 90 minutes after anaphylactic reactions. Serum tryptase concentration typically reaches a peak between 15 and 120 minutes, depending on the severity of the reaction, and is much more specific than histamine as a marker of anaphylactic reaction. It is highly suggestive of mast cell activation. Skin testing remains the gold standard for detection of the culprit agent.[77a] For many years, dilution thresholds have been debated. For instance, Laxenaire used a 1:10 dilution of rocuronium for interdermal skin testing,[212] whereas Rose and Fisher used a 1:1000 dilution.[209] Levy and associates showed that rocuronium in a 1:10 dilution can produce false-positive results in intradermal testing and suggested that rocuronium be diluted at least 100-fold to prevent such results.[213] The authors also reported that high concentrations ($\geq 10^{-4}$ M) of both rocuronium and cisatracurium were capable of producing a wheal-and-flare response to intradermal testing, which was associated with mild to moderate mast cell degranulation in the cisatracurium group only.[213] However, in contrast to control patients, skin tests with nondepolarizing NMBDs that were performed in patients who had an anaphylactic reaction were considered reliable. In the case of suspected anaphylactic reaction to any NMBD, it is mandatory to complete investigation for cross-reactivity with other commercially available NMBDs to identify safe alternative regimens.

All NMBDs can cause noncompetitive inhibition of histamine-*N*-methyltransferase, but the concentrations required for that inhibition greatly exceed those that would be used clinically, except in the case of vecuronium, with which the effect becomes manifest at 0.1 to 0.2 mg/kg.[214] This finding could explain the occurrence of occasional severe bronchospasm in patients after receiving vecuronium.[215] For goals of treatment of anaphylactic reactions, see Chapters 5 and 6.

DRUG INTERACTIONS AND OTHER FACTORS AFFECTING RESPONSE TO NEUROMUSCULAR BLOCKERS

A drug-drug interaction is an in vivo phenomenon that occurs when the administration of one drug alters the effects or kinetics of another drug. In vitro physical or chemical incompatibilities are *not* considered drug interactions.[216]

Many drugs interact with NMBDs or their antagonists, or both, and it is beyond the scope of this chapter to review them all.[216,217] Some of the more important drug interactions with NMBDs and their antagonists are discussed in the following sections.

Interactions Among Nondepolarizing Neuromuscular Blocking Drugs

Mixtures of two nondepolarizing NMBDs are considered to be either additive or synergistic. Antagonistic interactions have not been reported in this class of drugs. Additive interactions have been demonstrated after administration of chemically related drugs, such as atracurium and mivacurium,[218] or after coadministration of various pairs of steroidal NMBDs.[98] Conversely, combinations of structurally dissimilar (e.g., a steroidal with a benzylisoquinolinium) NMBDs, such as the combinations of pancuronium and dTc,[219] pancuronium and metocurine,[219] rocuronium and mivacurium,[142] or rocuronium and cisatracurium,[109] produce a synergistic response. An additional advantage (rapid onset and short duration) is noted for mivacurium-rocuronium combinations.[142] Although the precise mechanisms underlying a synergistic interaction are not known, hypotheses that have been put forward include the existence of multiple binding sites at the neuromuscular junction (presynaptic and postsynaptic receptors)[220] and the nonequivalence of binding affinities of the two α subunits (α_H and α_L). Further, inhibition of butyrylcholinesterase by pancuronium results in decreased plasma clearance of mivacurium and marked potentiation of the neuromuscular blockade.[221]

The pharmacodynamic response to the use of two different nondepolarizing NMBDs during the course of anesthesia depends not only on the specific drugs used but also on the sequence of their administration.[222,223] Approximately three half-lives are required for a clinical changeover (so that 95% of the first drug has been cleared) and for the duration of the blockade to begin to take on the characteristics of the second drug. After the administration of pancuronium, recovery from the first two maintenance doses of vecuronium is reportedly prolonged, although this effect becomes negligible by the third dose.[222] Similarly, Naguib and colleagues noted that the mean duration of the first maintenance dose of mivacurium to 10% recovery of the first twitch was significantly longer after atracurium (25 minutes) than after mivacurium (14.2 minutes).[218] However, the duration of the second maintenance dose of mivacurium after atracurium (18.3 minutes) was similar to that of mivacurium after mivacurium (14.6 minutes).

The apparent prolongation of action of the first maintenance dose of mivacurium administered after atracurium,[218] and of those reported with vecuronium after pancuronium,[222,223] is not related to synergism. Combinations of atracurium and mivacurium[218] and of vecuronium and pancuronium[98] are simply additive. However, this prolongation in the duration of action could be attributed to the relative concentrations of these drugs at the receptor site. Because most receptors remain occupied by the drug administered initially, the clinical profile depends on the kinetics or dynamics (or both) of the drug administered first, rather than on those of the second (maintenance)

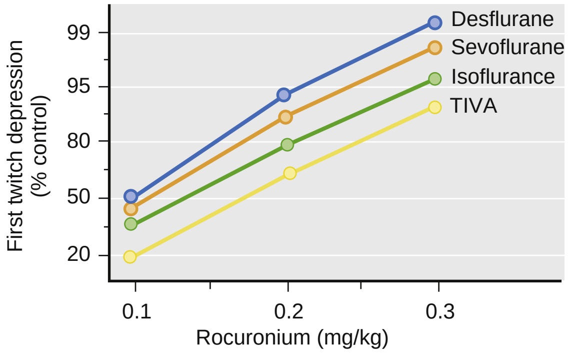

Fig. 27.15 Cumulative dose-response curves for rocuronium-induced neuromuscular blockade during 1.5 minimum alveolar concentration anesthesia with desflurane, sevoflurane, isoflurane, and total intravenous anesthesia *(TIVA)*. (From Wulf H, Ledowski T, Linstedt U, et al. Neuromuscular blocking effects of rocuronium during desflurane, isoflurane, and sevoflurane anaesthesia. *Can J Anaesth.* 1998;45:526–532, with permission from the *Canadian Journal of Anaesthesia*.)

drug. However, with further incremental doses of the second drug, a progressively larger proportion of the receptors is occupied by that second drug, and its clinical profile becomes evident.

Interactions Between Succinylcholine and Nondepolarizing Neuromuscular Blocking Drugs

The interaction between succinylcholine and nondepolarizing NMBDs depends on the order of administration and the doses used.[81,224,225] Small doses of different nondepolarizing NMBDs administered before succinylcholine to prevent fasciculations have an antagonistic effect on the development of subsequent depolarizing block produced by succinylcholine.[27,81] Therefore it is recommended that the dose of succinylcholine be increased after the administration of a defasciculating dose of a nondepolarizing NMBD.[27]

Studies of the effects of administering succinylcholine before nondepolarizing NMBDs have produced conflicting results. Several investigators reported potentiation of the effects of pancuronium,[224] vecuronium, and atracurium[225] by prior administration of succinylcholine. In contrast, other investigators found no significant influence of succinylcholine on subsequent administration of pancuronium, rocuronium, or mivacurium.[81,226,227]

Interactions With Inhaled Anesthetics

Deep anesthesia induced with potent volatile anesthetics (in the absence of neuromuscular blockade) may cause a slight reduction of neuromuscular transmission, as measured by depression of sensitive indicators of clinical neuromuscular function, such as tetanus and TOF ratio.[228] Inhaled anesthetics also enhance the neuromuscular blocking effects of nondepolarizing NMBDs. Inhaled anesthetics decrease the required dose of NMBDs, and prolong both the duration of action of the NMBD and recovery from neuromuscular block,[229] depending on the duration of anesthesia,[228,230,231] the specific inhaled anesthetic,[232] and the concentration (dose) given.[233] The rank order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide/barbiturate/opioid or propofol anesthesia (Fig. 27.15).[234-236]

The greater clinical muscle-relaxing effect produced by less potent anesthetics is mainly caused by their larger aqueous concentrations.[237] Desflurane and sevoflurane have low blood-gas and tissue-gas solubility, so equilibrium between the end-tidal concentration and the neuromuscular junction is reached more rapidly with these anesthetics than with older inhaled anesthetics.

The interaction between volatile anesthetics and NMBDs is one of pharmacodynamics, not pharmacokinetics.[238] The proposed mechanisms behind this interaction include (1) a central effect on α motoneurons and interneuronal synapses,[239] (2) inhibition of postsynaptic nAChR,[240] and (3) augmentation of the antagonist's affinity at the receptor site.[237]

Interactions With Antibiotics

Most antibiotics can cause neuromuscular blockade in the absence of NMBDs. The aminoglycoside antibiotics, the polymyxins, and lincomycin and clindamycin primarily inhibit the prejunctional release of acetylcholine and also depress postjunctional nAChR sensitivity to acetylcholine.[241] The tetracyclines, in contrast, exhibit postjunctional activity only. When combined with NMBDs, the aforementioned antibiotics can potentiate neuromuscular blockade.[242] The cephalosporins and penicillins have not been reported to potentiate neuromuscular blockade. Because antagonism of neuromuscular blockade with neostigmine has been reported to be more difficult after the administration of aminoglycosides,[243] ventilation should be controlled until the neuromuscular blockade terminates spontaneously. Ca^{2+} should not be used to hasten the recovery of neuromuscular function for two reasons: the antagonism it produces is not sustained, and it may prevent the antibacterial effect of the antibiotics.

Temperature

Hypothermia prolongs the duration of action of nondepolarizing NMBDs.[244-246] The force of contraction of the adductor pollicis decreases by 10% to 16% per degree Celsius decrease in muscle temperature lower than 35.2°C.[247,248] To maintain the muscle temperature at or higher than 35.2°C, the central temperature must be maintained above 36.0°C.[244] The mechanical response recovery to 10% twitch height with 0.1 mg/kg of vecuronium increases from 28 minutes at a mean central temperature of 36.4°C to 64 minutes at 34.4°C.[244] The mechanism or mechanisms underlying this prolongation may be pharmacodynamic or pharmacokinetic, or both.[246] They include diminished renal and hepatic excretion, changing volumes of distribution, altered local diffusion receptor affinity, changes in pH at the neuromuscular junction, and the net effect of cooling on the various components of neuromuscular transmission.[244,249] Hypothermia decreases the plasma clearance and prolongs the duration of action of rocuronium and vecuronium.[246] Temperature-related differences in the pharmacodynamics of vecuronium have also been reported. The k_{e0} decreases (0.023/min/°C) with lower temperature, a finding suggesting slightly delayed equilibration of drug between the circulation and the neuromuscular junction during hypothermia.[246] The Hofmann elimination process of atracurium is slowed by a decrease in pH and especially by a decrease in temperature.[250] In fact, atracurium's duration of action is markedly prolonged by hypothermia.[245] For instance, the duration of action of a dose of 0.5 mg/kg atracurium is 44 minutes at 37°C but 68 minutes at 34.0°C when evoked mechanical responses are monitored.

Changes in temperature also affect the interpretation of the results of monitoring neuromuscular blockade. For example, the duration of action of vecuronium measured in an arm cooled to a skin temperature of 27°C is prolonged, and monitoring by PTC in that arm is unreliable.[251] In the same patient, TOF responses are different if the arms are at different temperatures, and the correlation of responses in the two arms becomes progressively poorer as the temperature difference between the arms increases.[252]

The efficacy of neostigmine is not altered by mild hypothermia.[253-255] Hypothermia does not change the clearance, maximum effect, or duration of action of neostigmine in volunteers.[255] Mild hypothermia prolonged sugammadex reversal of deep rocuronium block by 46 seconds, a prolongation considered clinically acceptable.[255a]

Interactions With Magnesium and Calcium

Magnesium sulfate, given for treatment of preeclampsia and eclamptic toxemia, potentiates the neuromuscular blockade induced by nondepolarizing NMBDs.[256,257] After a dose of 40 mg/kg of magnesium sulfate, the ED_{50} of vecuronium was reduced by 25%, the onset time was nearly halved, and the recovery time nearly doubled.[257] Neostigmine-induced recovery is also attenuated in patients treated with magnesium.[256] The mechanisms underlying the enhancement of nondepolarizing block by magnesium probably involve both prejunctional and postjunctional effects. High magnesium concentrations inhibit Ca^{2+} channels at the presynaptic nerve terminals that trigger the release of acetylcholine.[16] Further, magnesium ions have an inhibitory effect on postjunctional potentials and cause decreased excitability of muscle fiber membranes. In patients receiving magnesium, the dose of nondepolarizing NMBDs must be reduced and carefully titrated using an objective monitor to ensure adequate recovery of neuromuscular function prior to tracheal extubation.

The interaction between magnesium and succinylcholine is controversial, with some reports suggesting that magnesium antagonizes the block produced by succinylcholine.[258] Ca^{2+} triggers the release of acetylcholine from the motor nerve terminal and enhances excitation-contraction coupling in muscle.[16] Increasing Ca^{2+} concentrations decreased the sensitivity to dTc and pancuronium in a muscle-nerve model.[259] In hyperparathyroidism, hypercalcemia is associated with decreased sensitivity to atracurium and thus a shortened time course of neuromuscular blockade.[260]

Interactions With Lithium

Lithium is used for treatment of bipolar affective disorder (manic-depressive illness). The lithium ion resembles Na^+, K^+, magnesium, and Ca^{2+} ions, and therefore may affect the distribution and kinetics of all these electrolytes.[261] Lithium enters cells via Na^+ channels and tends to accumulate within the cells.

By its activation of K^+ channels, lithium inhibits neuromuscular transmission presynaptically and muscular contraction postsynaptically.[262] The combination of lithium and pipecuronium results in a synergistic inhibition of neuromuscular transmission, whereas the combination of lithium and succinylcholine results in additive inhibition.[262] Prolongation of neuromuscular blockade was reported in patients taking lithium carbonate and receiving both depolarizing and nondepolarizing NMBDs.[263] Only one report did not demonstrate prolongation of recovery from succinylcholine in patients receiving lithium.[264] In patients who are stabilized on lithium therapy and undergoing surgery, NMBDs should be administered in incremental and reduced doses and titrated to the degree of blockade required.

Interactions With Local Anesthetic and Antidysrhythmic Drugs

Local anesthetics act on the presynaptic and postsynaptic part of the neuromuscular junction. In large intravenous doses, most local anesthetics block neuromuscular transmission; in smaller doses, they enhance the neuromuscular blockade produced by both nondepolarizing and depolarizing NMBDs.[265] The ability of neostigmine to antagonize a combined local anesthetic–neuromuscular blockade has not been studied. Procaine also inhibits butyrylcholinesterase and may augment the effects of succinylcholine and mivacurium by decreasing their hydrolysis by the enzyme.

In small intravenous doses, local anesthetics depress posttetanic potentiation, and this is thought to be a neural prejunctional effect.[266] With larger doses, local anesthetics block acetylcholine-induced muscular contractions, a finding suggesting that local anesthetics have a stabilizing effect on the postjunctional membrane.[267] Procaine displaces Ca^{2+} from the sarcolemma and thus inhibits caffeine-induced contracture of skeletal muscle.[268] Most of these mechanisms of action probably apply to all local anesthetics.

Several drugs used for the treatment of dysrhythmias augment the blockade induced by NMBDs. Single-fiber electromyography found that verapamil and amlodipine impair neuromuscular transmission in subjects without neuromuscular disease.[269] Clinical reports suggested potentiation of neuromuscular block with verapamil[270] and impaired reversal of vecuronium in a patient receiving disopyramide.[271] However, the clinical significance of these interactions is probably minor.

Interactions With Antiepileptic Drugs

Anticonvulsants have a depressant action on acetylcholine release at the neuromuscular junction.[272,273] Patients receiving long-term anticonvulsant therapy demonstrated resistance to nondepolarizing NMBDs (except mivacurium[274] and probably atracurium as well[273]), as evidenced by accelerated recovery from neuromuscular blockade and the need for increased doses to achieve complete neuromuscular blockade. Vecuronium clearance is increased two-fold in patients receiving long-term carbamazepine therapy.[275] Other investigators, however, attribute this resistance to the increased binding (i.e., decreased free fraction) of the NMBDs to α_1-acid glycoproteins or to upregulation of neuromuscular acetylcholine receptors (or to both mechanisms).[276] The latter could also explain the hypersensitivity seen with succinylcholine.[277] The slight prolongation of succinylcholine's action in patients taking anticonvulsants has few clinical implications. Conversely, the potential hyperkalemic response to succinylcholine in the presence of receptor upregulation is of concern.

Interactions With Diuretics

Early results showed that in patients undergoing renal transplantation, the intensity and duration of dTc neuromuscular blockade was increased after a dose of furosemide (1 mg/kg intravenously).[278]

Furosemide reduced the concentration of dTc required to achieve 50% twitch tension depression in the indirectly stimulated rat diaphragm and intensified the neuromuscular blockade produced by dTc and succinylcholine.[279] Furosemide appears to inhibit the production of cyclic adenosine monophosphate. In addition, the breakdown of adenosine triphosphate is inhibited, resulting in reduced output of acetylcholine. Acetazolamide antagonized the effects of anticholinesterases in the rat phrenic-diaphragm preparation.[280] However, in one report, 1 mg/kg of furosemide facilitated recovery of the evoked twitch response after pancuronium.[281] Long-term furosemide treatment had no effect on either dTc- or pancuronium-induced neuromuscular blockade.[282]

In contrast, mannitol appears to have no effect on a nondepolarizing neuromuscular blockade. Increasing urine output by the administration of mannitol or other osmotic or tubular diuretics has no effect on the rate at which dTc and presumably other NMBDs are eliminated in the urine.[283]

Interactions With Other Drugs

Dantrolene, a drug used for the treatment of malignant hyperthermia, prevents Ca^{2+} release from the sarcoplasmic reticulum and blocks excitation-contraction coupling. Although dantrolene does not block neuromuscular transmission, the mechanical response to stimulation is depressed, resulting in potentiation of nondepolarizing neuromuscular blockade.[284]

Azathioprine, an immunodepressant drug that is used in patients undergoing renal transplantation, has a minor antagonistic action on muscle relaxant–induced neuromuscular blockade.[285]

Steroids antagonize the effects of nondepolarizing NMBDs in both humans[286] and animals.[287] Possible mechanisms for this interaction include facilitation of acetylcholine release because of the effect of steroids on the presynaptic motor nerve terminal.[288] Other reports, however, described a noncompetitive inhibition and channel blockade of the nAChR.[289] Endogenous steroids act noncompetitively on nAChRs.[290] Prolonged treatment with a combination of corticosteroids and NMBDs can result in prolonged weakness in patients receiving critical care (see the later section on NMBDs and weakness syndromes in critically ill patients).

Antiestrogenic drugs such as tamoxifen appear to potentiate the effects of nondepolarizing NMBDs.[291]

Special Populations

PEDIATRIC PATIENTS

The development of the neuromuscular junction is not complete at birth.[16] In humans, maturation of neuromuscular transmission occurs after the first 2 months of age, although immature junctions have been found up to 2 years of age. The main evolution during the first months of life is that the fetal receptors located outside the neuromuscular junction will disappear and will be replaced by mature receptors with ε subunits instead of γ subunits. These changes suggest that that the neonate's neuromuscular junction may exhibit evidence of its immaturity by changes in response to NMBDs, although NMBDs can be used safely in term and preterm infants.

The routine administration of succinylcholine to healthy children should be discontinued. In apparently healthy children, intractable cardiac arrest with hyperkalemia, rhabdomyolysis, and acidosis may develop after succinylcholine administration, particularly in patients with unsuspected muscular dystrophy of the Duchenne type[292] (see the section on complications of succinylcholine).

Significant age-related differences in the potency of nondepolarizing NMBDs exist in infants and children when compared with adults. Children require higher doses of nondepolarizing NMBDs than any other age group of patients. In infants less than 1 year old, the ED_{95} at the adductor pollicis is approximately 30% less than in older children. It is not apparent from older studies whether the neonate is more sensitive than adults to nondepolarizing NMBDs,[293] although most of the studies showed a wider range of dosage requirement in the neonate. These apparent discrepancies have been explained in studies by Fisher and associates on the pharmacokinetics and pharmacodynamics of NMBDs in infants, children, and adults.[294-296] Neonates and infants are more sensitive than adults to the neuromuscular blocking effects of dTc.[294] Plasma concentrations required to achieve a desired level of neuromuscular blockade are 57% and 32% lower in neonates and infants, respectively, when compared with children. However, the dosage should not be decreased as much because neonates and infants have a larger volume of distribution at steady state. This increased volume of distribution results from the increase in extracellular fluid volume during the first months of life. This increase, in association with a lower elimination clearance, contributes to a longer elimination half-life.[294,297] In infants, less frequent dosing (longer dosing intervals) of nondepolarizing NMBDs may be required than in older children.

Atracurium, vecuronium, cisatracurium, rocuronium, and mivacurium are commonly administered to children because many surgical procedures are of short duration in children and are compatible with the duration of action of a single intubating dose. Onset time of neuromuscular block is faster in infants (30%) and children (40%) when compared with adults. This age-related effect is probably caused by circulatory factors such as the relative decrease in cardiac output and increase in circulation time with age.

As for long-acting NMBDs, the sensitivity of infants to vecuronium is greater than that of children (ED_{95} 0.047 mg/kg vs. 0.081 mg/kg, respectively).[298,299] An increased duration of action in infants is most likely secondary to the increased volume of distribution of vecuronium because its clearance is unchanged.[295,297] An age-dependent prolongation of action has been demonstrated in infants. A dose of 0.1 mg/kg of vecuronium produces almost a complete neuromuscular block of approximately 60 minutes' duration in infants but of only 20 minutes' duration in children and adults. Vecuronium therefore acts as a long-acting muscle NMBD in the neonate.[295,297]

In contrast, the duration of action of atracurium is not significantly different in the pediatric patient from that in the adult.[300] As with vecuronium and dTc, the volume of distribution is increased in infants.[296] However, the clearance of atracurium is also more rapid.[296] Therefore the same dose (0.5-0.6 mg/kg) can be used in infants, children, and adults for tracheal intubation without any major differences among the three groups in the drug's duration of action. Atracurium recovery from neuromuscular blockade is little affected by age in pediatric patients more than 1 month old. Histamine release and the occurrence of untoward reactions caused by atracurium are less frequent in children than in adults. In children, a dose of 0.1 μg/kg of cisatracurium has an onset just longer than 2 minutes and a clinical duration of approximately 30 minutes during balanced or halothane anesthesia.[301] The calculated ED_{95} doses of cisatracurium in infants and children are 43 and 47 μg/kg, respectively.[302] The mean infusion rate necessary to maintain 90% to 99% neuromuscular blockade is also similar in infants and children.[302]

Rocuronium in adults is an intermediate-acting NMBD with a faster onset of action than other nondepolarizing NMBDs, and this is also true in infants and children.[303,304] The ED_{95} is approximately 0.4 mg/kg in children; it is approximately 20% to 30% greater than that in adults, but its onset is faster in adults.[304] In children, 0.6 mg/kg of rocuronium produces better conditions for rapid tracheal intubation (approximately 60 seconds) than does 0.1 mg/kg of vecuronium (approximately 100 seconds) or 0.5 mg/kg of atracurium (approximately 180 seconds).[303] Evidence indicates that, even during sevoflurane induction in infants, the addition of 0.3 mg/kg rocuronium significantly improves intubating conditions and significantly decreases the frequency of respiratory adverse events such as desaturation because of laryngospasm during induction.[305] As with adults, for rapid sequence induction and intubation (60 seconds) in the presence of a full stomach, a 1.2 mg/kg dose of rocuronium is suggested to provide rapid, excellent intubating conditions in pediatric patients.

The rate of recovery of intermediate- or short-acting NMBDs is faster than that of long-acting drugs in children. A neostigmine dose of 30 μg/kg in children is quite comparable to the usual dose of 40 μg/kg in adults and provides satisfactory antagonism of nondepolarizing NMBD. Neostigmine-assisted recovery is dependent on age and is more rapid in children than either infants or adults.[305a] Several studies have demonstrated that when children's tracheas were extubated using clinical criteria of recovery, the TOF ratio did not exceed 0.50 to 0.60, whereas a TOF ratio greater than 0.90 is required to guarantee full recovery from neuromuscular block. These results highlight the need for objective (quantitative) assessment of neuromuscular block, even in infants and children, because of their sensitivity and variability in their responsiveness to nondepolarizing NMBDs.

OLDER PATIENTS

The pharmacodynamics of NMBDs may be altered in older patients. Physiologic changes such as decreases in total body water and lean body mass, increases in total body fat, decreases in hepatic and renal blood flow and hepatic enzyme activity, and decreases in glomerular filtration rate (≈20%/year in adults) typically accompany the aging process. These changes may account for the altered responses of older adults to NMBDs. Some physiologic and anatomic changes at the neuromuscular junction also occur with aging. These include an increase in the distance between the junctional axon and the motor end plate, flattening of the folds of the motor end plate, decreased concentration of acetylcholine receptors at the motor end plate, decrease in the amount of acetylcholine in each vesicle in the prejunctional axon, and decreased release of acetylcholine from the preterminal axon in response to a neural impulse.[16]

Several studies found no differences in the initial dose requirement for nondepolarizing muscle relaxants in older adults. The dose-response curves of atracurium, pancuronium, and vecuronium were shifted slightly to the right of the curves for the younger adult subjects; however, no significant differences were noted. After a bolus dose of pancuronium, no significant difference was observed in any of the plasma concentrations corresponding to a fixed degree of neuromuscular block. Such results confirm that nondepolarizing muscle relaxants are as potent in older as in young adult patients. The onset of neuromuscular block can be delayed and can be correlated with age.[306] This age-related effect is probably caused by circulatory factors such as the decrease in cardiac output and increase in circulation time in older adults. These factors induce slower biophase equilibration with plasma. The onset of rocuronium neuromuscular block was prolonged to 3.7 from 3.1 minutes in older adults. Similarly, the onset of cisatracurium is delayed approximately 1 minute in this age group.

A prolongation of the duration of action of nondepolarizing muscle relaxants and a decrease in dose requirements for the maintenance of neuromuscular block have been observed with several currently available muscle relaxants in older adults. These results are explained by pharmacokinetic changes in this population. The distribution and elimination may be altered by any of the multitude of physiologic changes that accompany the aging process. The effect of aging alone, as opposed to disease states often associated with the aging process, may be difficult to distinguish in identifying mechanisms of altered NMBD action in older adults.

Pancuronium,[307] vecuronium,[295,308] and rocuronium[177] depend on the kidney or the liver (or both) for their metabolism and elimination. Therefore they all show altered pharmacodynamics and pharmacokinetics in older patients. Pancuronium has delayed recovery in older adults because of decreased plasma clearance secondary to delayed urinary excretion. Vecuronium dose requirements to maintain a constant neuromuscular block are decreased by approximately 36% in patients older than 60 years, and spontaneous recovery is significantly longer in older patients.[25] Plasma clearance is reduced by more than 50% and elimination half-life prolonged by 60% in older patients.[308] The prolongation of vecuronium action appears to be secondary to decreased drug elimination consistent with age-associated decreases in hepatic and renal blood flows. The duration of action of rocuronium and the recovery index are also increased in older adults. The prolongation of action can be explained by a 27% decrease in plasma clearance.

In the case of drugs whose elimination is independent of hepatic or renal blood flow, pharmacokinetics and pharmacodynamics should not be altered significantly by age. Atracurium has multiple routes of elimination. Degradation by Hofmann elimination and ester hydrolysis is independent of the liver and the kidney and is not affected by age. The only pharmacokinetic change is a slight increase of the volume of distribution at steady state leading to a modestly increased elimination half-life. Consequently, the duration of action, the recovery index, and the dose requirement during a continuous infusion are independent of age. Cisatracurium is mainly eliminated by Hofmann elimination, and unlike atracurium, cisatracurium does not undergo hydrolysis by specific esterases. It exhibits a slightly delayed onset of effect in older patients because of slower biophase equilibration. Clearances are not decreased in patients of advanced age. The slight prolongation of the elimination half-life of the drug in older adults is secondary to an increased volume of distribution at steady state (+10%). These minor pharmacokinetic changes are not associated with changes in the recovery profile in older patients.

Butyrylcholinesterase activity in older adults, although still in the normal range, is approximately 26% lower than that in young adults.[309] Because mivacurium is metabolized by butyrylcholinesterase, its clearance is likely to be slightly reduced in older patients, thus resulting in a 20% to 25% longer duration of action,[310] as well as a decreased infusion requirement to maintain a stable depth of block. Succinylcholine metabolism is unaffected by these changes.

In general, when maintaining neuromuscular blockade with nondepolarizing NMBDs in older patients, one can expect that, with the exception of atracurium and cisatracurium, the dosing interval will be increased to maintain the desired depth of neuromuscular blockade. The choice of drug and monitoring the depth of blockade are exceptionally important in this population because recovery of neuromuscular function is generally delayed in older patients. Inadequate or incomplete recovery of muscle strength after the use of pancuronium is associated with an increased incidence of perioperative pulmonary complications in this patient population.[129] The clear relationship between incomplete recovery from neuromuscular block and occurrence of critical respiratory events in the PACU highlights the need for objective monitoring to ensure recovery of neuromuscular block in older patients.

OBESE PATIENTS

The level of plasma pseudocholinesterase activity and the volume of extracellular fluid, which are the main determinants of the duration of action of succinylcholine, are increased in obese patients. For complete neuromuscular paralysis and predictable intubating conditions, a 1-mg/kg dose based on total-body weight (TBW) is recommended.[311]

Initial studies showed that obese subjects needed significantly more pancuronium than nonobese patients to maintain a constant 90% depression of twitch height. However, when corrected for body surface area (BSA), no significant difference was noted in dose requirement to maintain neuromuscular block.

The use of NMBDs with an intermediate duration of action should be preferred. Vecuronium doses based on TBW induce a prolonged duration of action in obese patients, although vecuronium pharmacokinetics is unaltered by obesity. The prolonged recovery in obese patients can be explained by the larger total dose of vecuronium administered to these patients. With larger doses, when administration is based on TBW, recovery occurs during the elimination phase when plasma concentration decreases more slowly than during the distribution phase.[312] The pharmacokinetics of rocuronium is not altered by obesity. In the same way, the duration of action of rocuronium is significantly prolonged when the dose is calculated according to TBW. In contrast, when rocuronium is dosed according to ideal body weight (IBW), the clinical duration is less than half.[313,314]

A correlation exists between the duration of action of atracurium and TBW when the dose is given as milligrams per kilogram of TBW. The clinical duration of action is doubled when the drug is given based on TBW versus IBW. There is little difference between obese and normal-weight patients in atracurium elimination half-life (19.8 vs. 19.7 minutes), volume of distribution at steady state (8.6 vs. 8.5 L), and total clearance (444 vs. 404 mL/min).[315] The finding that IBW avoids prolonged recovery of atracurium-induced blockade can be explained by an unchanged muscle mass and an unchanged volume of distribution in morbidly obese patients compared with normal-weight patients.[316] The duration of cisatracurium is also prolonged in obese patients when the drug is given on the basis of TBW versus IBW.

In summary, nondepolarizing NMBDs should be given to obese patients on the basis of IBW rather than on their actual body weight, to ensure that these patients are not receiving relative overdoses and to avoid prolonged recovery. When using maintenance doses, objective monitoring is strongly recommended to avoid accumulation.

SEVERE RENAL DISEASE

NMBDs contain quaternary ammonium groups that make them very hydrophilic. They are therefore usually completely ionized at a pH of 7.4 and are poorly bound to plasma proteins. The predominant pathway of elimination of steroidal muscle relaxants is ultrafiltration by the glomeruli before urinary excretion. Renal failure influences the pharmacologic characteristics of nondepolarizing NMBDs by producing either decreased renal elimination of the drug or its metabolites. Only atracurium, cisatracurium, and, to some extent, vecuronium are independent of renal function. Succinylcholine elimination is mainly independent of kidney function. However, succinylcholine is metabolized by plasma cholinesterases, and concentrations may be slightly decreased in patients with severe renal failure (Table 27.11). The decrease in plasma cholinesterase activity is always moderate (30%) and does not result in prolongation of succinylcholine-induced neuromuscular block. Succinylcholine induces a transient increase in plasma K^+ concentration (<0.5 mmol/L). Therefore succinylcholine is not contraindicated in severe renal failure when plasma K^+ concentrations are within the normal range. The duration of action of NMBDs may be prolonged in patients with renal failure.

Renal failure does not alter the sensitivity (dose response) of patients to the neuromuscular blocking action of pancuronium,[317] atracurium,[318] vecuronium,[319] or rocuronium.[320] All long-acting muscle relaxants are eliminated predominantly through the kidney, and renal failure is associated with reduced plasma clearance and increased elimination half-life for these drugs as well.[103] The elimination half-life of pancuronium is increased by 500% in patients with severe renal failure. As a consequence of these

pharmacokinetic changes, the duration of neuromuscular blockade produced by these drugs is longer and more variable than in patients with normal renal function. Because of the potential for prolonged blockade and the availability of intermediate- and short-acting NMBDs, long-acting NMBDs should not be used in patients with renal failure.

The pharmacokinetics and duration of action of atracurium are unaffected by renal failure.[321,322] This lack of effect is in part because Hofmann elimination and ester hydrolysis[173] account for 50% of its total clearance.[167] Laudanosine, the principal metabolite of atracurium, is eliminated unchanged by the kidney. The elimination half-life of laudanosine increases in renal failure.[322] Even during continuous administration of atracurium, laudanosine plasma concentrations are 10 times lower than concentrations associated with seizures in dogs.

In patients with chronic renal failure, the duration of action of cisatracurium is not prolonged.[323] Hofmann elimination accounts for 77% of the total clearance of cisatracurium,[169] and renal excretion accounts for 16% of its elimination.[169] The peak plasma laudanosine concentration is 10 times lower than after equipotent doses of atracurium. In patients with end-stage renal failure, the volume of distribution is unchanged, but there is a 13% reduction in clearance and an increase from 30 to 34 minutes in elimination half-life.

Vecuronium relies principally on hepatic mechanisms for its elimination. However, its clearance is reduced and its elimination half-life is increased in patients with renal failure.[324,325] In one study, the duration of action of 0.1 mg/kg of vecuronium was both longer and more variable in patients with renal failure than in those with normal renal function.[325] In three other studies, the duration of action of 0.05 to 0.14 mg/kg of vecuronium was not prolonged by renal failure, but this result was likely caused by the use of relatively small doses or inadequate sample sizes.[324] The principal metabolite of vecuronium, 3-desacetylvecuronium, has 80% of the neuromuscular blocking activity of vecuronium[153]; it may cause prolonged paralysis in patients with renal failure in the ICU.[156] In patients with renal failure, the duration of action and the rate of recovery from vecuronium- or atracurium-induced neuromuscular blockade during surgery are similar.[326]

The major routes of elimination of rocuronium are biliary and urinary excretion. Rocuronium is taken up by the liver and metabolized, excreted, or both, in bile and feces in high concentrations. After 0.6 mg/kg rocuronium, up to one fifth of the dose is recovered unchanged from the urine within 24 hours, and no active metabolites can be found in humans. Pharmacokinetic studies showed that the clearance of rocuronium was reduced by 33% to 39% in patients with renal failure.[326a] The distribution volume of this drug remained unchanged or slightly increased.[175] The elimination half-life was 70 and 57 minutes in patients with and without renal failure, respectively. The duration of action of single and repeated doses, however, was not affected significantly.[320]

In renal failure, there is no significant change in the volume of distribution of neostigmine. The clearance is decreased by two thirds and the elimination half-life is

prolonged from 80 to 183 minutes in patients with renal failure. The clearance of edrophonium is also significantly reduced and its elimination half-life significantly prolonged in patients with end-stage renal failure.

HEPATOBILIARY DISEASE

In comparison with renal elimination, liver function is a modest determinant of the pharmacokinetics of nondepolarizing muscle relaxants. The influence of hepatobiliary disease on the pharmacokinetics of NMBDs can be complex because of the different types of liver failure (Table 27.12). Cirrhosis is associated with an increased extracellular water compartment, edema, and, often, kidney dysfunction. Cholestasis induces decreased biliary excretion but is not associated with significant liver failure, contrary to acute hepatic failure.

A delayed onset of action and an apparent resistance to nondepolarizing muscle relaxants occur in patients with cirrhosis, although studies demonstrated that the sensitivity of the neuromuscular junction was unaltered. This is the consequence of the increased volume of distribution, which induces greater dilution of muscle relaxants in cirrhotic patients. The increase of terminal half-life can be secondary to either the increased volume of distribution or decreased biliary excretion for muscle relaxants dependent on hepatic function for elimination.[154] Following a single dose of nondepolarizing muscle relaxant, in most of the cases, no prolongation of the duration of action occurs because it is dependent on distribution. However, for muscle relaxants dependent on hepatic elimination, prolongation of neuromuscular block can be observed following repeated doses or continuous infusion.

Pancuronium is mainly eliminated through the kidney, although one third of the dose is metabolized and excreted through the liver. The elimination half-life increases from 114 to 208 minutes in cirrhotic patients.[150] This is the consequence of a 50% increase of the volume of distribution in conjunction with a 22% decrease in plasma clearance.[150] Cholestasis induces a 50% decrease in pancuronium clearance leading to a prolonged elimination half-life of 270 minutes. Severe acute hepatic failure also induces reduced plasma clearance and a prolonged elimination half-life.

Vecuronium elimination is mainly through the bile.[326b] Only a small fraction is metabolized to 3-hydroxyvecuronium, which still has 60-80% of the potency of vecuronium. This metabolic process is presumed to occur in the liver because 40% of the total dose of vecuronium is found in the liver and bile as both parent drug and metabolite.[147] The elimination half-life is increased in mildly decompensated cirrhotic patients as the result of a decreased clearance,[154] whereas the volume of distribution of the central compartment and the volume of distribution at steady state can be increased. In cirrhotic patients, the duration of action of vecuronium is related to the dose. A dose of 0.1 mg/kg has a slower onset of action and a shorter duration of action because the volume of distribution is increased. In contrast, after 0.2 mg/kg vecuronium, the duration of action is increased from 65 minutes to 91 minutes in cirrhotic patients because elimination is impaired. Cholestasis can increase plasma concentration of bile salts and thus reduce the hepatic uptake of vecuronium,[147] as well as pancuronium. This may explain the decreased clearance observed by some investigators. The duration of action of vecuronium is increased by 50% in patients with biliary obstruction.

Rocuronium is mainly excreted into the bile. The volume of both the central compartment (+33%) and the volume of distribution at steady state (+43%) are increased in cirrhotic patients, whereas clearance may be decreased.[326c] The duration of action is prolonged in patients with hepatic disease, and a correlation exists between the increased volume of distribution and the slower onset of action when compared with controls.[176]

Atracurium and cisatracurium share organ-independent modes of elimination.[165,168,169] As a consequence, their clearance should be little affected by hepatic disease. In fact, and in contrast to all other NMBDs, the plasma clearances of atracurium and cisatracurium are slightly increased in patients with liver disease (see Table 27.12).[174,180] Because elimination of atracurium and cisatracurium occurs outside of, as well as from within, the central compartment, investigators have suggested that a larger distribution volume should be associated with greater clearance.[169] In two studies,[174,180] volumes of distribution and clearances of the drugs increased with liver disease, thereby lending support to this hypothesis.[169] The increased clearance of the relaxant in patients with liver disease is not reflected in a decrease in the drug's duration of action.[174,180]

One concern raised about administering atracurium to patients with hepatic disease is the possible accumulation of laudanosine. Although laudanosine relies principally on hepatic mechanisms for its elimination, the concentrations encountered during liver transplantation are unlikely to be associated with clinical sequelae.[327]

Because of the wide interindividual variations seen in the response to nondepolarizing muscle relaxants in patients with hepatic disease, quantitative monitoring of neuromuscular block is required, with careful titration of doses.

In patients with severe liver disease, butyrylcholinesterase activity is decreased because of decreased synthesis of the hepatic enzymes. Consequently, the plasma clearance of the isomers of mivacurium is decreased by approximately 50% (see Table 27.12),[159] and the drug's duration of action is prolonged and may be almost tripled.[159]

TABLE 27.13 Conditions Associated With Upregulation and Downregulation of Acetylcholine Receptors

nAChR Upregulation	nAChR Downregulation

Guillain-Barré syndrome	

nAChR, Nicotinic acetylcholine receptor.

BURNS

In patients with burn injuries, muscle relaxants can be used to facilitate mechanical ventilation, which can be associated with sustained improvement in oxygenation. After a period of immobilization, burn injury causes upregulation of both fetal ($\alpha_2\beta\gamma\delta$) and mature ($\alpha_2\beta\varepsilon\delta$) nAChRs.[328] This upregulation of nAChRs usually is associated with resistance to nondepolarizing NMBDs and increased sensitivity to succinylcholine.[329] Causes of upregulation of nAChRs are listed in Table 27.13. A significant increase in the quantal content of evoked acetylcholine release is typically noted by 72 hours after scald injury in rats.[330] This increase also contributes to the resistance to NMBDs in patients with burn injuries. In mice, thermal injury induces changes in diaphragm acetylcholinesterase with respect to total content and specific molecular forms.[331]

Resistance to the effects of nondepolarizing NMBDs is usually seen in patients with burns over at least 25% of their total BSA.[329,332,333] Recovery of neuromuscular function to preburn levels may take several months or even years after the burn injury.[334] The increase in serum K^+ concentration that normally follows succinylcholine administration is markedly exaggerated in burned patients and may be lethal.[335] K^+ concentrations as high as 13 mEq/L, resulting in ventricular tachycardia, fibrillation, and cardiac arrest, have been reported.[335] The magnitude of the hyperkalemic response does not appear to correlate closely with the magnitude of the burn injury. Potentially lethal hyperkalemia was seen in a patient with only an 8% total BSA burn.[336] Succinylcholine has been safely administered within 24 hours of a burn injury. It can be used for prehospital or emergency room intubation. After an initial 24-hour interval, however, sufficient alteration in muscle response may have occurred. Because of the unpredictability of occurrence of hyperkalemia, the use of succinylcholine is best avoided after 24 hours following a burn injury.

The time course of abnormal muscle membrane function corresponds with that of the healing process. Once normal skin has regrown and any infection subsides, the normal acetylcholine receptor populations appear to return.[334] Although normal responses to succinylcholine have been demonstrated in burned patients studied 3 years after injury,[334] the actual length of time during which a patient

BOX 27.1 Reported Indications for the Use of Muscle Relaxants in the Intensive Care Unit

- Facilitation of mechanical ventilation
  - Facilitation of endotracheal intubation
  - Enabling patient to tolerate mechanical ventilation
  - High pulmonary inflation pressures (e.g., acute respiratory distress syndrome)
- Hyperventilation for increased intracranial pressure
- Facilitation of therapeutic or diagnostic procedures
- Tetanus
- Status epilepticus
- Reduction of oxygen consumption
  - Abolishing shivering
  - Reduction of work of breathing

with a burn injury may be at risk for the hyperkalemic response is not well defined. A conservative guideline therefore would be to avoid the use of succinylcholine in patients 24 hours after a thermal injury and for at least 1 or 2 years after the burned skin has healed.

USE OF NEUROMUSCULAR BLOCKING DRUGS AND WEAKNESS SYNDROMES IN CRITICALLY ILL PATIENTS

NMBDs are frequently used in conjunction with sedatives and analgesics in ICUs. The indications for the use of NMBDs in the ICU are outlined in Box 27.1. Few available data support their use, and evidence for a beneficial effect on pulmonary function or patient oxygenation is inconclusive.[337] However, a multicenter, double-blind trial showed that, in a subset of patients with acute respiratory distress syndrome, early and short-term administration of cisatracurium for 48 hours could be beneficial.[338] Half of the patients in the placebo group in that study received one or more doses of cisatracurium. The study was underpowered, and the effect on mortality was statistically borderline, with no between-group difference in crude mortality rate. Yet, nondepolarizing NMBDs are sometimes used in ICU patients. Of particular concern in intensive-care settings is the risk that paralyzed patients receive inadequate analgesia and sedation.[339] This reason for this concern may be that ICU nurses and physicians are unfamiliar with the pharmacology of the NMBDs.[339,340] For instance, pancuronium was thought to be an anxiolytic by 50% to 70% of ICU nurses and house staff, and 5% to 10% thought it was an analgesic.[339] In the United Kingdom, the erroneous use of NMBDs as sedatives in intensive care was not uncommon in the 1980s.[341] Approximately 96% of ICU patients received NMBDs to aid mechanical ventilation in 1980. By 1986, their use had decreased to 16% of ventilated patients.[341] Currently, intensivists are aware of the side effects and generally avoid administration of NMBDs to critically ill ICU patients. Clinical practice guidelines for management of critically ill adults who require neuromuscular paralysis have been published.[341a] Specific indications for the use of NMBDs in the ICU setting include severe, refractory hypoxemia; suppression of shivering during therapeutic hypothermia after cardiac arrest; elimination of unwanted movement in patients with status asthmaticus, high intracranial or intraabdominal pressure, massive hemoptysis, or to facilitate short procedures such as bronchoscopy or endoscopy; and acute respiratory failure in patients who require emergent tracheal intubation.[341a]

BOX 27.2 Complications of Muscle Paralysis in the Intensive Care Unit

- Short-term use
  - Specific, known drug side effects
  - Inadequate ventilation in the event of a ventilator failure or circuit disconnection
  - Inadequate analgesia and/or sedation
- Long-term use
  - Complications of immobility
    - Deep vein thrombosis and pulmonary embolus
    - Peripheral nerve injuries
    - Decubitus ulcers
- Inability to cough
  - Retention of secretions and atelectasis
  - Pulmonary infection
- Dysregulation of nicotinic acetylcholine receptors
- Prolonged paralysis after stopping relaxant
  - Persistent neuromuscular blockade
  - Critical illness myopathy
  - Critical illness polyneuropathy
  - Combination of the above
- Unrecognized effects of drug or metabolites
  - Succinylcholine and metabolic acidosis or hypovolemia
  - 3-Desacetylvecuronium and neuromuscular blockade
  - Laudanosine and cerebral excitation

A prolonged ICU stay during critical illness is associated with disorders of neuromuscular function that contribute to morbidity, length of hospital stay, weaning difficulties, and prolonged rehabilitation.[342] The complications of long-term administration of NMBDs in the ICU are outlined in Box 27.2. In the ICU, duration of mechanical ventilation, sepsis, the dysfunction of two or more organs, female sex, administration of steroids, and hypercapnia are known risk factors for developing neuromuscular dysfunction. Syndromes of weakness in critically ill patients are relatively common and likely polymorphic in origin. In a retrospective study of 92 critically ill patients with clinically diagnosed weakness, electromyographic studies indicated that acute myopathy (critical illness myopathy [CIM]) is three times as common as acute axonal neuropathy (critical illness neuropathy): 43% versus 13%, respectively.[342] The additional healthcare cost of a single case of persistent weakness was estimated at approximately $67,000.[343] Conditions to consider when making a differential diagnosis of neuromuscular weakness in the ICU are listed in Box 27.3.

Critical Illness Myopathy

Lacomis and colleagues suggested using the term CIM,[344] instead of the current terms used in the literature, such as acute quadriplegic myopathy,[345] acute (necrotizing) myopathy of intensive care, thick filament myopathy, acute corticosteroid myopathy, and critical care myopathy.

Initial published reports of CIM in the ICU focused on patients with status asthmaticus[346] who typically had been treated with corticosteroids and nondepolarizing NMBDs.

BOX 27.3 **Causes of Generalized Neuromuscular Weakness in the Intensive Care Unit**

- Central nervous system
  - Septic or toxic-metabolic encephalopathy
  - Brainstem stroke
  - Central pontine myelinolysis
  - Anterior horn cell disorders (e.g., amyotrophic lateral sclerosis)
- Peripheral neuropathies
  - Critical illness polyneuropathy
  - Guillain-Barré syndrome
  - Porphyria
  - Paraneoplasia
  - Vasculitis
  - Nutritional and toxic neuropathies
- Neuromuscular junction disorders
  - Myasthenia gravis
  - Lambert-Eaton myasthenic syndrome
  - Botulism
  - Prolonged neuromuscular junction blockade
- Myopathies
  - Critical illness myopathy
  - Cachectic myopathy
  - Rhabdomyolysis
  - Inflammatory and infectious myopathies
  - Muscular dystrophies
  - Toxic myopathies
  - Acid maltase deficiency
  - Mitochondrial
  - Hypokalemia
  - Hypermetabolic syndromes with rhabdomyolysis (e.g., neuroleptic malignant syndrome)

From Lacomis D. Critical illness myopathy. *Curr Rheumatol Rep.* 2002;4:403–408.

Nevertheless, myopathy has also been documented in asthmatic patients and in patients with chronic lung disease without paralysis who received corticosteroids,[347] as well as in critically ill patients with sepsis who received neither corticosteroids nor nondepolarizing NMBDs.[348] The primary cause of this condition is a loss of myosin in myocytes with subsequent loss of contractile capacity. Animal studies also reveal that the number of cytosolic corticosteroid receptors is increased in immobilized muscles relative to that in contralateral controls.[349] It seems—at least in some patients—that prolonged immobility may be the key risk factor for myopathy in corticosteroid-treated patients,[350] and selective muscle atrophy is a result of changes in glucocorticoid sensitivity.[349]

Sepsis, immobility, and the catabolism associated with negative nitrogen balance may also result in myopathy.[16] Skeletal muscle hypoperfusion is noted in patients with severe sepsis despite normal or elevated whole blood oxygen delivery.[351] Antibodies to nAChRs were demonstrated in a rodent model of sepsis.[352] Thus myasthenia-like syndrome is also seen in critically ill patients. Evidence for local immune activation by cytokine expression in the skeletal muscle was reported in patients with CIM.[353]

The major feature of CIM is flaccid weakness that tends to be diffuse and sometimes also includes the facial muscles and diaphragm.[344] The clinical features of CIM overlap with those of critical illness polyneuropathy (CIP) and prolonged neuromuscular blockade.[344] Electrophysiologic studies and increases in serum creatine kinase concentrations may differentiate neuropathy from myopathy.[344] Lacomis and colleagues stated, “muscle biopsy should be considered if another myopathic process such as an inflammatory myopathy is suspected or if the histologic findings would affect management.”[344]

Critical Illness Polyneuropathy

CIP is the polyneuropathy seen in critically ill patients. It affects both sensory and motor nerves and occurs in 50% to 70% of patients with multisystem organ failure and systemic inflammatory response syndrome.[354] Investigators have postulated that systemic inflammatory response syndrome contributes to CIP by releasing cytokines and free radicals that damage the microcirculation of the central and peripheral nervous systems.[353] Dysregulation of the microcirculation may render the peripheral nervous system susceptible to injury.

Although no pharmacologic treatment for muscle weakness syndromes in the critically ill patient currently exists, increasing evidence indicates the positive effects of early physical rehabilitation during ICU stay. Previously, intensive insulin therapy during critical illness was found to decrease the risk of CIP, and the maintenance of blood glucose at or below 110 mg/mL in critically ill patients may reduce the risk of CIP.

The outcomes from CIM and CIP appear to be similar. The reported mortality rate of patients with CIP syndrome is approximately 35%. In one study, 100% (13 of 13) of the patients who survived had abnormal clinical or neurophysiologic findings 1 to 2 years after the onset of the CIP syndrome, and quality of life was markedly impaired in all patients.[355]

Clinical Implications

Nondepolarizing NMBDs are the most common chemical agents producing immobilization and inducing a denervation-like state. In such circumstances, besides the mature or junctional nAChR formed of two α and one each of β, ε, and δ subunits, two other isoforms, the immature AChR or γAChR and the neuronal α7AChR, are expressed in the muscle. The immature AChR is also referred to as extrajunctional because it is expressed mostly in the extrajunctional part of the muscle. Upregulation of nAChRs was noted in the muscles of deceased critically ill adults who had received long-term infusions of vecuronium.[356] Upregulation refers to changes in the number of available receptors, but these changes usually do not involve a change in isoform configuration. These three types of receptors can coexist in the muscle.

Should Succinylcholine Be Used in Patients in the Intensive Care Unit?

It is likely that upregulation of nAChRs induced by immobilization and by prolonged administration of nondepolarizing NMBDs contributes to (1) the higher incidence of cardiac arrest associated with the use of succinylcholine in ICU patients[356] and (2) increased requirements for nondepolarizing NMBDs in ICU patients.[357] Even more important, succinylcholine more easily depolarizes immature nAChRs that may induce profound outward K^+ flux, with subsequent hyperkalemia. Moreover, the α7AChR can also be depolarized by succinylcholine, thus contributing to the K^+ efflux from the cell to the extracellular space. Therefore succinylcholine should be avoided in ICU patients in whom total body immobilization exceeds 24 hours.[16]

Should Nondepolarizing Neuromuscular Blocking Drugs Be Used in Patients in the Intensive Care Unit?

NMBD-associated persistent weakness appears to be a distinct pathologic entity and is not simply a manifestation of weakness syndromes in critically ill patients. In a prospective study, there was a 70% incidence of persistent weakness in ICU patients who received NMBDs for more than 2 days, compared with a 0% incidence in similar ICU patients who received no NMBD.[358] This is compelling evidence for the effects of nondepolarizing NMBDs in this complication.

Long-term weakness has been described after nondepolarizing NMBDs.[156,359,360] Approximately 20% of patients who received NMBDs for more than 6 days,[359] 15% to 40% of asthmatic patients who also received high-dose steroids,[346] and 50% of patients with renal failure who received vecuronium developed prolonged weakness.[156] Clinically, it appears that prolonged recovery from neuromuscular blockade occurs more frequently when steroidal NMBDs are used.[156,359]

However, prolonged weakness was also noted after the use of atracurium in ICU patients.[360] Further, the use of atracurium has raised concerns about its metabolite, laudanosine. Laudanosine, also detected in the cerebrospinal fluid (CSF) of ICU patients given atracurium,[361] is an analeptic and can trigger seizures in animals.[362] The toxic dose in humans is not known, but case reports have noted patients having seizures while receiving atracurium, and laudanosine has not been ruled out as a cause of these seizures.[363-365] Evidence also indicates that laudanosine can activate neuronal nicotinic receptors.[366] Cisatracurium is a single isomer of atracurium, and because it is four to five times more potent than atracurium, it is given in smaller total doses. Therefore the risk of laudanosine-related adverse effects should be minimal.[367]

Nondepolarizing NMBDs are polar molecules and do not readily cross the blood-brain barrier, but vecuronium and its long-acting active metabolite, 3-desacetylvecuronium, have been detected in the CSF of patients in the ICU. The CNS effects of NMBDs and their metabolites in humans have not been well studied, but in rats, atracurium, pancuronium, and vecuronium injected into the CSF caused dose-related cerebral excitation culminating in seizures.[362] Cerebral excitation with consequent increased cerebral oxygen demand is undesirable in ICU patients at risk of cerebral ischemia. Investigators have also suggested that nondepolarizing NMBDs can gain access to nerves during systemic inflammatory response syndrome, thus resulting in direct neurotoxicity.[362]

When nondepolarizing NMBDs are necessary, the use of an objective neuromuscular monitor is recommended, and periodic return of muscle function should be allowed. Adjusting the dosage of NMBDs by peripheral nerve stimulation versus standard "clinical dosing" in critically ill patients reduces drug requirements, produces faster recovery of neuromuscular function, and is cost-effective.[369] Daily interruption of sedative-drug infusions decreases the duration of mechanical ventilation and the length of stay in the ICU.[370] The effect of such an approach on the weakness syndromes in the ICU patient is unknown. When nondepolarizing NMBDs are used, the guidelines in Box 27.4 may help minimize the incidence of complications. As stated in the clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient,[337] "*Independent of the reasons for using neuromuscular blockers, we emphasize that all other modalities to improve the clinical situation must be tried, using neuromuscular blockers only as a last resort*. To this admonition, we would add a plea that clinicians use objective monitors, whenever possible, to guide NMBD administration and assess readiness for tracheal extubation, whether in the operating room or ICU settings. The unquestionable benefits of quantitative neuromuscular monitoring are described in Chapter 43.

BOX 27.4 Recommendations for the Use of Neuromuscular Blockers in the Intensive Care Unit

- Avoid the use of neuromuscular blockers by
  - Maximal use of analgesics and sedatives
  - Manipulation of ventilatory parameters and modes
- Minimize the dose of neuromuscular blocker
  - Use a peripheral nerve stimulator with train-of-four monitoring
  - Do not administer for more than 2 days continuously
  - Administer by bolus rather than infusion
  - Administer only when required and to achieve a well-defined goal
  - Continually allow recovery from paralysis
  - Consider alternative therapies

Acknowledgment

The editors and publisher would like to thank Drs. Mohamed Naguib and Cynthia A. Lien for contributing a chapter on this topic in the prior edition of this work. It has served as the foundation for the current chapter.

Reversal (Antagonism) of Neuromuscular Blockade

GLENN MURPHY, HANS D. DE BOER, LARS I. ERIKSSON, AND
RONALD D. MILLER

KEY POINTS

- Appropriate reversal of a nondepolarizing neuromuscular blockade is essential to avoid adverse patient outcomes. Complete recovery of muscle strength should be present, and the residual effects of neuromuscular blocking drugs (NMBDs) should be fully pharmacologically reversed (or spontaneously recovered).
- Sufficient recovery from neuromuscular blockade for tracheal extubation can be confirmed by an adductor pollicis train-of-four (TOF) ratio of at least 0.90 (or 1.0 if acceleromyography [AMG] is used). Quantitative neuromuscular monitoring is the only method of assessing whether a safe level of recovery of muscular function has occurred.
- Residual neuromuscular blockade is not a rare event in the postanesthesia care unit (PACU). Approximately 30% to 50% of patients can have TOF ratios less than 0.90 following surgery.
- Patients with TOF ratios less than 0.90 in the PACU are at increased risk for hypoxemic events, impaired control of breathing during hypoxia, airway obstruction, postoperative pulmonary complications, symptoms of muscle weakness, and prolonged PACU admission times. Appropriate management of neuromuscular blockade can decrease the incidence of, or eliminate, residual blockade, which will reduce the risks of these adverse postoperative events.
- Neostigmine, pyridostigmine, and edrophonium inhibit the breakdown of acetylcholine, resulting in an increase in acetylcholine in the neuromuscular junction. However, there is a “ceiling” effect to the maximal concentration of acetylcholine that can be achieved with these drugs. Reversal of neuromuscular blockade with anticholinesterases should not be attempted until some evidence of spontaneous recovery is present. Neostigmine in the dose range of 30 to 70 μg/kg body weight antagonizes moderate to shallow levels of neuromuscular blockade. However, if these reversal drugs are given in the presence of full neuromuscular recovery, paradoxical muscle weakness theoretically may be induced.
- Sugammadex is a modified γ-cyclodextrin that shows a high affinity for the steroidal NMBDs rocuronium and vecuronium. Sugammadex is able to form a tight inclusion complex with either of these steroidal NMBDs, thereby inactivating the effects of rocuronium and vecuronium, resulting in rapid reversal of neuromuscular blockade.
- Sugammadex is able to reverse a moderate/shallow and a profound neuromuscular blockade with a dose of 2.0 mg/kg and 4.0 mg/kg, respectively. An immediate reversal of neuromuscular blockade induced by rocuronium is possible with a dose of sugammadex 16 mg/kg. Reversal of neuromuscular blockade by sugammadex is rapid and without many of the side effects encountered with anticholinesterase drugs.
- Fumarates (gantacurium [GW280430A, AV430A], CW002, and CW011) represent a new class of NMBDs in development that are inactivated primarily via adduction of cysteine to the double bond of the compounds, resulting in inactive breakdown products. Laboratory studies have shown that the administration of exogenous L-cysteine results in complete reversal of deep neuromuscular blockade within 2 to 3 minutes.

History

The paralytic effects of curare have been recognized since the time of Sir Walter Raleigh’s voyage on the Amazon in 1595.[1] In 1935, the name *d*-tubocurarine was assigned to an alkaloid isolated from a South American vine *(Chondrodendron tomentosum)*. At approximately the same time, experiments from pharmacology and physiology laboratories in London suggested that acetylcholine was the chemical neurotransmitter at motor nerve endings.[2] Investigations from these same laboratories demonstrated that eserine (physostigmine)-like substances could reverse the effects of curare at the neuromuscular junction of frog nerve-muscle preparations.[2] In the clinical setting, Bennett (1940) described the use of curare in the prevention of traumatic complications during convulsive shock therapy.[3] In 1942, Griffith and colleagues reported on the effects of an extract of curare in 25 surgical patients; all patients appeared to recover fully without administration of an antagonist such as neostigmine.[4]

The importance of pharmacologic reversal of neuromuscular blockade was suggested in 1945. Specifically, use of neostigmine or physostigmine to antagonize curare was recognized and was recommended to be available whenever muscle relaxants were given in the operating room.[5] The first large case series examining the use of curare was published by Cecil Gray in 1946.[1] A crystalline extract, *d*-tubocurarine chloride, was administered in 1049 general anesthesia cases. No postoperative complications directly attributable to *d*-tubocurarine were noted, and physostigmine was administered to only two patients in the series. However, in a later review article (1959) from the same anesthesia department, the authors concluded that "it is safer to always use neostigmine when nondepolarizing relaxants have been administered."[6] By the mid-1960s, significant differences in neuromuscular management existed between the United States and Europe. As noted in an editorial from this time, "In Great Britain the majority of anesthetists have arbitrarily adopted the attitude that the dangers of reversal are far less than those of latent paresis, so that most patients receive at least some anticholinesterase drug at the end of anesthesia." In the United States, however, where smaller doses of curare were used, the emphasis was more on the mortality and morbidity associated with reversal drugs. Of greater importance was the use of muscle relaxants in smaller doses so that reversal drugs were not necessary.[7] In fact, in the senior author's training (Miller), the prevailing thinking was that emphasis in anesthesia should be on "properly anesthetizing rather than paralyzing" a patient; it was commonly said that "curare is not an anesthetic."

Despite more than seven decades of research, significant differences in opinion still exist regarding management of neuromuscular blockade at the conclusion of surgery and anesthesia. On a routine basis, some clinicians pharmacologically antagonize a nondepolarizing neuromuscular blocking drug (NMBD), whereas others antagonize neuromuscular blockade only when obvious clinical muscle weakness is present. The issue is whether clinically important weakness exists when it is not clinically apparent. Will monitoring of neuromuscular blockade improve patient care? The aim of this chapter is to review the consequences of incomplete neuromuscular recovery, the use of anticholinesterase drugs in clinical practice (benefits, risks, and limitations), and the recent developments in novel drugs to reverse/antagonize residual neuromuscular blockade.

Antagonism of Neuromuscular Blockade: Current Management Practices

A number of survey studies have been conducted to determine how clinicians evaluate and manage neuromuscular blockade in the perioperative period. In the late 1950s, a survey was sent to anesthetists in Great Britain and Ireland.[6] Forty-four percent of the respondents used neostigmine "always" or "almost always" when *d*-tubocurarine chloride or gallamine was used. Two thirds of respondents administered 1.25 to 2.5 mg when antagonizing these NMBDs.[6] Despite accumulating data demonstrating a continued frequent incidence of residual neuromuscular blockade, more-recent surveys indicate that attitudes toward reversal of neuromuscular blockade have changed little over the intervening decades. A questionnaire sent to German anesthesiologists in 2003 revealed routine reversal with neostigmine at the end of surgery was not practiced in 75% of anesthesia departments.[8] A similar survey of 1230 senior anesthetists in France reported that pharmacologic antagonism of neuromuscular blockade was "systematic" or "frequent" in only 6% and 26% of surgical cases, respectively.[9] In contrast, reversal of nondepolarizing NMBDs was routinely performed in Great Britain.[10]

A large-scale, comprehensive survey of neuromuscular management practices in the United States and Europe was conducted in order to better understand attitudes about doses of NMBDs, monitoring, and pharmacologic reversal.[11] Only 18% of European respondents and 34.2% of respondents from the United States "always" administered an anticholinesterase drug when a nondepolarizing relaxant was used. The findings from these surveys suggest that there is little agreement about best practices related to reversal of neuromuscular blockade. Despite perioperative guidelines from several international and national organizations, surveys from many countries reveal that most clinicians do not monitor or reverse a neuromuscular blockade in the operating room. Surprisingly, most anesthesiologists have not witnessed obvious adverse events directly attributable to incomplete recovery from neuromuscular blockade.[11] Therefore the potential hazards of reversal of neuromuscular blockade using an anticholinesterase drug (see later) are likely estimated to be more frequent than the risks of residual neuromuscular blockade. In the following sections, the definitions, incidence, and clinical implications of residual neuromuscular blockade are reviewed.

RESIDUAL NEUROMUSCULAR BLOCKADE

Assessment of Residual Neuromuscular Blockade

In order to optimize patient safety, tracheal extubation in the operating room should not occur until complete recovery of muscle strength is present and the residual effects of NMBDs have been fully reversed (or spontaneously recovered). Therefore methods to detect and treat residual muscle weakness are essential in improving postoperative outcomes. Three methods are commonly used in the operating room to determine the presence or absence of residual neuromuscular blockade: clinical evaluations for signs of muscle weakness, qualitative neuromuscular monitors (peripheral nerve stimulators), and quantitative (objective) neuromuscular monitors. A more detailed description of the types of neuromuscular monitors used perioperatively is provided in Chapter 43.

Clinical Evaluation for Signs of Muscle Weakness. Following the introduction of *d*-tubocurarine into clinical practice, residual paralysis and the need for neostigmine was determined primarily by the observation of "shallow, jerky movements of the diaphragm" at the end of surgery.[12] In the absence of any clinically observable respiratory impairment, neuromuscular function was assumed to be adequate, and no reversal drugs were administered. A peripheral nerve stimulator to assess neuromuscular

TABLE 28.1 Sensitivity, Specificity, Positive, and Negative Predictive Values of an Individual Clinical Test for a Train-of-Four <90% in 640 Surgical Patients

Variable	Sensitivity	Specificity	Positive Predictive Value	Negative Predictive Value
Inability to smile	0.29	0.80	0.47	0.64
Inability to swallow	0.21	0.85	0.47	0.63
Inability to speak	0.29	0.80	0.47	0.64
General weakness	0.35	0.78	0.51	0.66
Inability to lift head for 5 s	0.19	0.88	0.51	0.64
Inability to lift leg for 5 s	0.25	0.84	0.50	0.64
Inability to sustain hand grip for 5 s	0.18	0.89	0.51	0.63
Inability to perform sustained tongue depressor test	0.22	0.88	0.52	0.64

The sensitivity of a test is the number of true positives ÷ the sum of true positives + false negatives; the specificity is the number of true negatives ÷ the sum of true negatives + false positives. True positives are patients scoring positive for a test and having a train-of-four (TOF) <90%. False negatives are patients with a negative test result but a TOF <90%. True negatives have a negative test score and a TOF not <90%; false positives score positively but have a TOF not <90%. A *positive* test result means *inability* to smile, swallow and speak, general muscular weakness, and so on.

From Cammu G, De Witte J, De Veylder J, et al. Postoperative residual paralysis in outpatients versus inpatients. *Anesth Analg*. 2006;102:426–429.

blockade was first used in the 1960s by Harry Churchill-Davidson in the United Kingdom and later in the United States. However, routine use of a peripheral nerve stimulator did not occur. In fact, several decades later, the most commonly applied technique for evaluation of recovery of neuromuscular function continues to be the use of clinical tests for signs of apparent muscle weakness.[13] Furthermore, one of the primary factors that determines whether clinicians elect to administer a reversal drug at the end of surgery is the presence of signs of muscle weakness.[11] However, for decades an array of clinical studies from different countries have consistently shown that tests of muscle strength are not sensitive or reliable indices of adequate neuromuscular recovery. The most commonly applied criteria used to determine suitability for extubation of the trachea are a "normal" pattern of ventilation and a sustained head lift.[13] Unfortunately, the sensitivity of each test in detecting residual blockade is poor. At a level of neuromuscular recovery that allows for adequate ventilation in a patient whose trachea is intubated, the muscles responsible for maintaining airway patency and protection are significantly impaired.[14] Other investigators have observed that the majority of subjects could maintain a 5-second head lift at a train-of-four (TOF) ratio of 0.50 or less.[15,16] Additional clinical tests of muscle strength, such as sustained hand-grip, leg-lift, or eye opening, have been demonstrated to have a low sensitivity in predicting recovery of neuromuscular function (Table 28.1).[17,18]

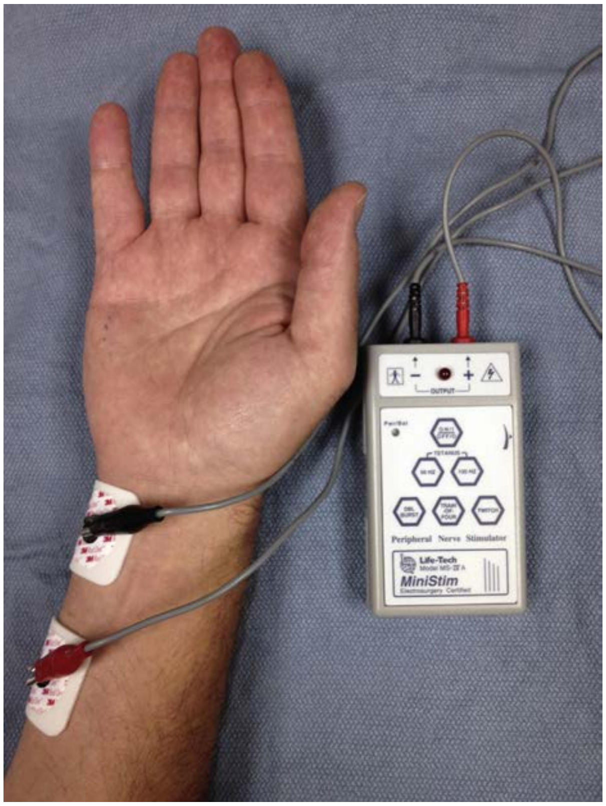

Fig. 28.1 Example of a qualitative neuromuscular monitor (or more appropriately, a peripheral nerve stimulator). (MiniStim, Halyard Health, Roswell, GA) A peripheral nerve is stimulated, and the response to nerve stimulation is subjectively (qualitatively) assessed using either visual or tactile (hand placed on the muscle) means. In this illustration, the ulnar nerve is stimulated, and movement of the thumb subjectively evaluated.

Qualitative Neuromuscular Monitoring. Qualitative neuromuscular monitors—or more accurately, peripheral nerve stimulators—deliver an electrical stimulus to a peripheral nerve, and the response to nerve stimulation is subjectively assessed by clinicians either visually or tactilely (i.e., placing a hand on the thumb to detect the muscle contraction after ulnar nerve stimulation) (Fig. 28.1). Three patterns of nerve stimulation are used in the clinical setting to assess patients for residual blockade: TOF, tetanic, and double-burst stimulation. TOF stimulation delivers four supramaximal stimuli every 0.5 seconds, tetanic stimulation consists of a series of extremely rapid (usually 50 or 100 Hz) stimuli typically applied over 5 seconds, and double-burst stimulation delivers two short bursts of 50-Hz tetanic stimuli separated by 750 ms. The presence of fade with these patterns of nerve stimulation indicates incomplete neuromuscular recovery. Although qualitative monitoring may guide management during early recovery from neuromuscular blockade, the sensitivity of these devices in detecting small degrees of

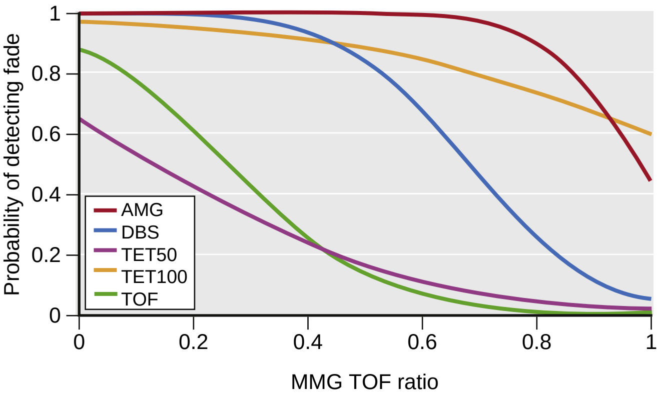

Fig. 28.2 Detection of fade with various neuromuscular monitoring techniques. Residual neuromuscular blockade was evaluated using acceleromyography *(AMG)*, tactile assessment of train-of-four *(TOF)*, double-burst stimulation *(DBS)*, 50-Hz tetanus *(TET50)*, or 100-Hz tetanus *(TET100)*. The mechanomyographic *(MMG)* adductor pollicis TOF ratio was measured at one extremity. During recovery, a blinded observer estimated tactile fade in the other extremity. Probability of detection of fade by logistic regression is presented. (From Capron F, Fortier LP, Racine S, Donati F. Tactile fade detection with hand or wrist stimulation using train-of-four, double-burst stimulation, 50-hertz tetanus, 100-hertz tetanus, and acceleromyography. *Anesth Analg.* 2006;102:1578–1584.)

residual paresis (TOF ratios between 0.50 and 1.0) is limited (Fig. 28.2). When using TOF stimulation, investigators have consistently observed that clinicians are unable to detect fade when TOF ratios exceed 0.30 to 0.40.[19-21] Similarly, the observation of fade during a 5-second, 50-Hz tetanic stimulation is difficult when TOF ratios are greater than 0.30.[21,22] The ability of clinicians to detect fade is improved with double-burst stimulation; the threshold for detection of fade is approximately 0.6 to 0.7 using this mode of stimulation.[20,21,23] However, regardless of the mode of nerve stimulation used, residual neuromuscular blockade cannot always be reliably excluded using qualitative monitoring.

Quantitative Neuromuscular Monitoring. Quantitative neuromuscular monitors are instruments that permit both stimulation of a peripheral nerve and the quantification and recording of the evoked response to nerve stimulation. Quantitative monitors allow an accurate assessment of the degree of muscle weakness using either TOF stimulation (TOF ratio displayed) or single-twitch stimulation (response compared with control “twitch” as a percentage). Although five different methods of quantifying neuromuscular function in the operating room have been developed, only one technology, acceleromyography (AMG, available as the Stimpod, Xavant Technology, Pretoria, South Africa), is commercially obtainable as a stand-alone monitor. The portable TOF-Watch AMG monitor (Bluestar Enterprises, San Antonio, Texas), which has been used in the majority of published clinical trials, is no longer sold in the United States (Fig. 28.3). In a study comparing AMG with standard qualitative tests (tactile fade to TOF, double-burst, 5-Hz tetanic, and 100-Hz tetanic stimulation), AMG was the most accurate technique in detecting residual paralysis (see Fig. 28.2).[21] In addition, the use of AMG in the operating room has been demonstrated to reduce the risk of residual neuromuscular blockade in the postanesthesia care unit (PACU)[24-27] and to decrease adverse respiratory events and symptoms of muscle weakness associated with incomplete neuromuscular recovery.[26,27] In clinical practice, AMG is a valuable monitor in determining whether full recovery of neuromuscular function has occurred before tracheal extubation, and provides objective data to guide dosing of reversal drugs at the conclusion of surgery (see later).

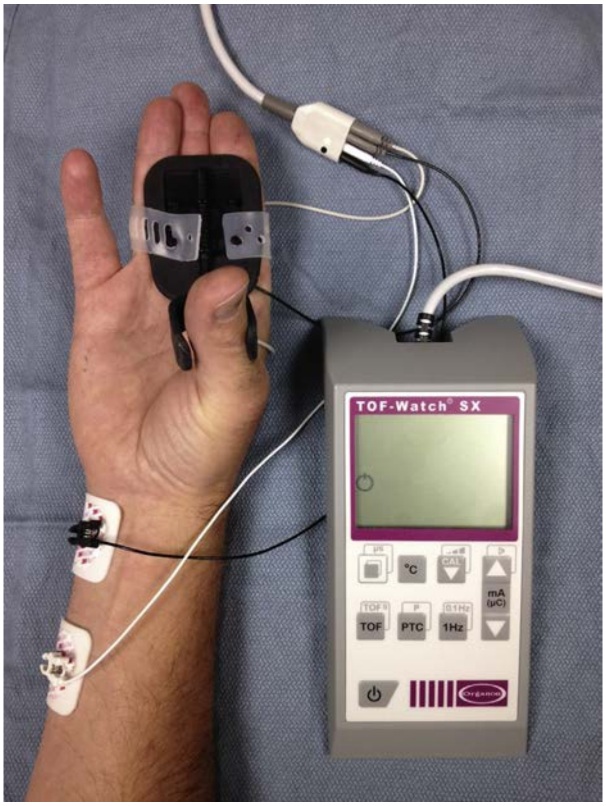

Fig. 28.3 Example of a quantitative neuromuscular monitor (acceleromyography). (TOF-Watch AMG, Bluestar Enterprises, San Antonio, TX) Ulnar nerve stimulation results in thumb movement, which is sensed by a piezoelectric sensor attached to the thumb. To improve the consistency of responses, a hand adapter applies a constant preload. Acceleration of the thumb is sensed by the piezoelectric sensor, and is proportional to the force of muscle contraction.

A careful evaluation of the degree of residual blockade at the conclusion of a general anesthetic is essential in order to avoid the potential hazards of incomplete neuromuscular recovery following tracheal extubation. However, the methods used by most clinicians (ability to perform a head lift or maintain a stable pattern of ventilation; no fade observed to TOF or tetanic nerve stimulation) are insufficient in assuring safe recovery. At the present time, quantitative neuromuscular monitoring is the only method of determining whether full recovery of muscular function has occurred and reversal drugs safely avoided. In order to exclude with certainty the possibility of residual paresis, quantitative monitoring should be used. For a more comprehensive description of neuromuscular monitoring see Chapter 43.

Definitions of Residual Neuromuscular Blockade

QUANTITATIVE NEUROMUSCULAR MONITORING: TOF RATIO LESS THAN 0.70 AND LESS THAN 0.90 Traditionally, residual neuromuscular blockade has been defined using quantitative neuromuscular monitoring. Although peripheral nerve stimulation was used in the 1960s, Ali and colleagues first described the application of peripheral nerve stimulation for neuromuscular monitoring using the ulnar nerve–adductor pollicis unit as the site of monitoring in the early 1970s.[28,29] By comparing the amplitude of the fourth (T4) to the first (T1) evoked mechanical or electromyographic response (TOF response), the degree of neuromuscular recovery could be measured. Shortly thereafter, these same investigators performed several studies examining the association between the degree of residual blockade in the hand (defined using quantified T4/T1 ratio, i.e., TOF ratio) with symptoms of peripheral muscle weakness and spirometry measurements.[30-32] At adductor pollicis TOF ratios less than 0.60, signs of muscle weakness, tracheal tug, and ptosis were observed. When TOF ratios recovered to 0.70, the majority of patients were able to sustain head lift, eye opening, hand grasp, tongue protrusion, and a vital capacity exceeding 15 mL/kg. On the basis of these data, a TOF ratio of 0.70 was previously agreed on to represent acceptable neuromuscular recovery at the end of a general anesthetic that included administration of nondepolarizing NMBDs. Yet, more recently, clinically significant muscle weakness and impaired respiratory control have been observed at TOF ratios of up to 0.90. At TOF ratios less than 0.90, awake volunteers exhibit impaired pharyngeal function, airway obstruction, an increased risk of aspiration of gastric contents, an impaired hypoxic ventilatory control, and unpleasant symptoms of muscle weakness.[33-37] In surgical patients, an association between TOF ratios less than 0.90 and adverse respiratory events and prolonged PACU length of stay has been observed.[38,39] At the present time, it is generally agreed that adequate recovery of neuromuscular function is represented by an adductor pollicis TOF ratio of at least 0.90 (or even 1.0 when AMG is used).

Clinical Signs and Symptoms. A variety of clinical signs may be present in patients with residual neuromuscular blockade, including the following: inability to perform a head lift, hand grip, eye opening, or tongue protrusion; inability to clench a tongue depressor between the incisor teeth; inability to smile, swallow, speak, cough, track objects with eyes; or inability to perform a deep or vital capacity breath.[40] Symptoms of residual blockade that have been reported include subjective difficulty performing the aforementioned tests, as well as blurry vision, diplopia, facial weakness, facial numbness, and general weakness.[37,40] Although the majority of patients with TOF ratios of 0.90 to 1.0 will have recovered satisfactory strength in most muscle groups, signs and symptoms of muscle weakness may be present in some of these patients. In contrast, a few patients with significant residual blockade (TOF ratios < 0.70) may exhibit no apparent muscle weakness. The most inclusive and precise definition of residual neuromuscular blockade should include not only objective and quantifiable monitoring data (a TOF ratio < 0.90 demonstrated with AMG, mechanomyography [MMG], or electromyography [EMG]) but also clinical evidence of impaired neuromuscular recovery (swallowing impairment, inability to speak or perform a head lift, diplopia, and/or general weakness).

Incidence of Residual Neuromuscular Blockade

Residual neuromuscular blockade is not a rare event in the PACU. In 1979, Viby-Mogensen examined the efficacy of neostigmine in reversing *d*-tubocurarine, gallamine, or pancuronium blockade.[41] On arrival to the PACU, 42% of patients had a TOF ratio less than 0.70, and 24% were unable to perform a 5-second head lift (the majority of these subjects had TOF ratios <0.70). The authors concluded that the average dose of neostigmine given (2.5 mg) was insufficient for reversing neuromuscular blockade. Subsequent studies demonstrated a similarly frequent incidence of residual blockade in patients receiving long-acting NMBDs; 21% to 50% of patients in the early postoperative period had TOF ratios less than 0.70.[42-44] Subsequently, the risk of postoperative residual blockade was reduced if intermediate-acting NMBDs were used instead of long-acting drugs.[44-46] As the use of long-acting NMBDs began to decrease in clinical practices, many investigators hoped that residual blockade would become an uncommon occurrence in the PACU. However, incomplete neuromuscular recovery continues to be a common postoperative event. Large-scale studies (150–640 subjects) have demonstrated that approximately 31% to 50% of patients have clinically significant residual neuromuscular blockade with adductor pollicis TOF ratios less than 0.90 following surgery.[17,47,48] A recent multicenter investigation enrolling 1571 patients from 32 centers documented that 58% of patients had TOF ratios less than 0.90 at the time of tracheal extubation, despite the use of neostigmine reversal in 78% of subjects.[49]. In a metaanalysis of data from 24 clinical trials, Naguib and colleagues calculated the incidence of residual blockade by NMBD type and TOF ratio.[44] The pooled rate of residual blockade, defined as a TOF ratio less than 0.90, was 41% when studies using intermediate-acting NMBDs were analyzed (Table 28.2). In conclusion, a frequent incidence

of residual neuromuscular blockade still occurs worldwide in the immediate postoperative period; with current practice and inadequate monitoring, the incidence of this complication is not decreasing over time.

The observed incidence of postoperative residual blockade varies widely between studies, ranging from 5% to 93%.[44] A number of factors may influence the degree of neuromuscular recovery measured following tracheal extubation, accounting for the reported variability in the incidence of residual blockade (Box 28.1). The observed incidence of residual blockade is more frequent if a threshold definition of 0.90 is used (vs. the previous threshold of 0.70) (see Table 28.2). Similarly, a frequent incidence of residual paralysis is observed if there is a short time interval between reversal of NMBDs and quantification of TOF ratios (TOF ratios measured at the time of extubation vs. measurement in the PACU).[50] Furthermore, the technology used to quantify neuromuscular recovery may influence the percentage of patients with TOF ratios less than 0.90 following surgery. For example, when compared with MMG, AMG frequently overestimates the degree of neuromuscular recovery.[21] Additional factors influencing the degree of residual paralysis are discussed later.

Adverse Effects of Residual Blockade

Many investigations have demonstrated that approximately one half of patients will be admitted to the PACU with TOF ratios less than 0.90, as measured with AMG, MMG, or EMG.[44] The impact of this residual muscle weakness on clinical outcomes has been less well documented. Yet even minimal levels of neuromuscular blockade may have clinical consequences. The following section reviews the effects of residual blockade in both awake volunteer studies and in postoperative surgical patients.

Adverse Effects of Residual Blockade—Awake Volunteer Studies. Surgical patients receive a variety of anesthetics in the perioperative period, which complicates an assessment of the particular effect of residual neuromuscular blockade on clinical outcomes. Conducting awake volunteer trials allows investigators to more precisely quantify the impact of NMBDs and various degrees of neuromuscular blockade on physiologic systems in the absence of anesthetics. In general, these studies have titrated NMBDs to various TOF ratios in awake subjects and measured the effects on the respiratory system and on signs and symptoms of muscle weakness.

Early volunteer investigations concluded that respiratory impairment was minimal at TOF ratios of 0.60 to 0.70.[32] Respiratory frequency, tidal volume, vital capacity, and peak expiratory flow rates were not altered during the study, although vital capacity and inspiratory force were both significantly reduced compared with control values at a TOF ratio of 0.60.[32] The authors concluded that these changes were of minor clinical importance. Subsequent investigations have revealed that pharyngeal and respiratory function is impaired at TOF ratios as high as 0.90 to 1.0. Return of pharyngeal muscle function is essential for airway control following tracheal extubation. In series of human studies from the Karolinska Institutet, Sweden, a

BOX 28.1 Factors Influencing the Measured Incidence of Postoperative Residual Neuromuscular Blockade

Preoperative Factors

1. Definition of residual neuromuscular blockade
   - TOF ratio < 0.70 (before 1990)
   - TOF ratio < 0.90 (after 1990)
   - Presence of signs or symptoms of muscle weakness
2. Patient factors
   - Age (higher risk in older adults)
   - Gender
   - Preexisting medical conditions (renal or liver dysfunction, neuromuscular disorders)
   - Medications known to affect neuromuscular transmission (antiseizure medications)

Intraoperative Anesthetic Factors

1. Type of NMBD administered intraoperatively
   - Intermediate-acting NMBD (lower risk)
   - Long-acting NMBD (higher risk)
2. Dose of NMBD used intraoperatively
3. Use of neuromuscular monitoring
   - Qualitative monitoring (studies inconclusive)
   - Quantitative monitoring (lower risk)
4. Depth of neuromuscular blockade maintained
   - "Deeper blockade" (TOF count of 1-2) (higher risk)
   - "Lighter blockade" (TOF count of 2-3) (lower risk)
5. Type of anesthesia used intraoperatively
   - Inhalational agents (higher risk)
   - TIVA (lower risk)

Factors Related to Antagonism of Residual Blockade

1. Use of reversal agents (lower risk)
   - Neostigmine
   - Pyridostigmine
   - Edrophonium
   - Sugammadex
2. Dosage of reversal agent used
3. Time interval between reversal agent administration and quantification of residual blockade

Factors Related to Measurement of Residual Blockade

1. Method of objective measurement of residual neuromuscular blockade
   - Mechanomyography (MMG)
   - Electromyography (EMG)
   - Acceleromyography (AMG)
   - Kinemyography (KMG)
   - Phonomyography (PMG)
2. Time of measurement of residual neuromuscular blockade
   - Immediately

Postoperative Factors

1. Respiratory acidosis and metabolic alkalosis (higher risk)
2. Hypothermia (higher risk)
3. Drug administration in the PACU (antibiotics, opioids) (higher risk)

NMBD, Neuromuscular blocking drug; *PACU*, postanesthesia care unit; *TIVA*, total intravenous anesthetic; *TOF*, train-of-four.

functional assessment of the pharynx, upper esophageal muscles, and the integration of respiration with swallowing was performed during various levels of neuromuscular blockade.[33-34] At adductor pollicis TOF ratios less than 0.90, pharyngeal dysfunction was observed in 17% to 28% of young adult volunteers (Fig. 28.4),[33] increasing more than twofold in patients older than 60 years and associated with reduced upper esophageal sphincter resting tone and misdirected swallowing and aspiration (laryngeal penetration) of oral contrast material.[33,34,51] Eikermann and colleagues conducted a series of investigations examining the effect of residual paresis on respiratory muscle function in awake volunteers. Awake subjects were administered a rocuronium infusion, which was titrated to a TOF ratio 0.50 to 1.0. At a minimal level of residual blockade (approximately 0.80), the authors observed impaired inspiratory air flow and upper airway obstruction,[35] a marked decrease in upper airway volumes and upper airway dilator muscle function,[52] and increased upper airway closing pressure and collapsibility (Fig. 28.5).[53] In addition, evidence from human studies of respiratory control suggest that residual blockade inhibits hypoxic ventilatory control while leaving the ventilatory control during hypercapnia unaffected. In human volunteers, the hypoxic ventilatory response was attenuated by 30% after administration of either atracurium, vecuronium, or pancuronium at an adductor pollicis TOF ratio of 0.70, returning to normal after spontaneous recovery to a TOF ratio of greater than 0.90 (Fig. 28.6).[54] An increase in ventilatory drive during hypoxia is primarily mediated by afferent input from peripheral chemoreceptors in the carotid bodies located bilaterally at the carotid artery bifurcation, whereas ventilatory regulation during hypercapnia is mediated via CO_2 interaction with brainstem chemoreceptors. In experimental animals, the firing frequencies of carotid body chemoreceptors are almost abolished by the administration of a nondepolarizing NMBD via blockade of cholinergic neuronal subtype receptors within the carotid body oxygen signaling pathway.[55]

Awake volunteer studies have also revealed that unpleasant symptoms of muscle weakness are present in subjects with small degrees of residual neuromuscular blockade. Conscious subjects given a small "priming" dose of pancuronium noted blurred vision, difficulty swallowing, and keeping their eyes open, and jaw weakness at a TOF ratio of 0.81.[56] Symptoms of diplopia, dysarthria, and subjective difficulty swallowing were reported by subjects at TOF ratios of 0.60 and 0.70.[34] Reduced clarity of vision was described in all subjects receiving a mivacurium infusion at a TOF ratio of 0.81.[57] Kopman and associates examined 10 volunteers

Fig. 28.5 An investigation examining the effect of residual neuromuscular blockade on respiratory muscle function in awake volunteers. Subjects were administered a rocuronium infusion, which was titrated to a train-of-four *(TOF)* ratio 0.5 to 1.0. Supraglottic airway diameter and volume was measured by respiratory-gated magnetic resonance imaging. Minimum retroglossal upper airway diameter during forced inspiration (A) before neuromuscular blockade (baseline), at a steady-state TOF ratio of (B) 0.50 and (C) 0.80, (D) after recovery of the TOF ratio to 1.0, and (E) 15 minutes later. Images from the volunteer show that a partial paralysis evokes an impairment of upper airway diameter increase during forced inspiration. $P < .05$ versus baseline. (From Eikermann M, Vogt FM, Herbstreit F, et al. The predisposition to inspiratory upper airway collapse during partial neuromuscular blockade. *Am J Respir Crit Care Med.* 2007;175:9–15.)

for symptoms and signs of residual paralysis at various TOF ratios.[37] Testing was performed at baseline (before an infusion of mivacurium), at a TOF ratio of 0.65 to 0.75, at 0.85 to 0.95, and at full recovery (1.0). All subjects had significant signs and symptoms at a TOF ratio of 0.70 (inability to maintain incisor teeth apposition, sit without assistance, drink from a straw, visual disturbances, facial numbness, difficulty speaking and swallowing, general weakness), and in seven subjects, visual symptoms persisted for up to 90 minutes after the TOF ratio had recovered to unity.

Adverse Effects of Residual Blockade—Postoperative Surgical Patients. Awake volunteers have impairment of respiratory function and a variety of symptoms of muscle weakness at TOF ratios of 0.50 to 0.90. Similar adverse events have been observed in postoperative surgical patients with TOF ratios less than 0.90 measured in the PACU. Incomplete neuromuscular recovery is a risk factor for hypoxemic events, airway obstruction, unpleasant symptoms of muscle weakness, delayed PACU length of stay, and pulmonary complications during the early postoperative period.

Clearly, an association exists between neuromuscular management characteristics and postoperative morbidity and mortality. Beecher and colleagues collected data from 10 university hospitals between the years 1948 to 1952 to determine anesthetic-related causes of mortality.[58] Risk of death related to anesthesia was six times more frequent in patients receiving NMBDs (primarily tubocurarine and decamethonium) compared with those administered no NMBDs (1:370 vs. 1:2100). Although the authors conclude that there is "an important increase in anesthesia death rate when muscle relaxants are added"[58] to an anesthetic, the use or omission of pharmacologic reversal in patients receiving NMBDs was not reported or analyzed. In another large-scale study, mortality data associated with anesthesia were collected over a 10-year period (1967-1976) at a single institution in South Africa.[59] An analysis of 240,483 anesthetics revealed that "respiratory inadequacy following myoneural blockade" was the second-most common cause of death. Again, data relating to the use of pharmacologic reversal drugs were not provided. A study from the Association of Anaesthetists of Great Britain and Ireland examined deaths that were judged "totally due to anesthesia" and reported that postoperative respiratory failure secondary to neuromuscular management was a primary cause of mortality.[60] Rose and associates examined patient, surgical, and anesthetic factors associated with critical respiratory events in the PACU.[61] Of the anesthetic management factors assessed, the most frequent rate of critical respiratory events was observed in patients receiving large doses of NMBDs (the use of reversal drugs was not analyzed). Two investigations of anesthetic complications resulting in admissions to the intensive care unit determined that "failure to reverse after muscle relaxants" and "ventilatory inadequacy after reversal of muscle relaxants" were the most common causes of admission.[62,63] Sprung and colleagues reviewed the medical records of patients who experienced a cardiac arrest over a 10-year period (223 of 518,284 anesthetics).[64] The most important category was the use of NMBDs, involving either hypoxia caused by inadequate pharmacologic reversal or asystole induced by anticholinesterase drugs. A large case-control investigation was performed of all patients undergoing anesthesia over a 3-year period (n = 869,483) in The Netherlands assessing the impact of anesthetic management characteristics on the risk of coma or death within 24 hours of surgery.[65] Reversal of the effects of NMBDs was associated with a significant reduction (odds ratio, 0.10; 95% confidence interval [CI], 0.03-0.31) in the risk of these complications. Two studies published in 2016 and 2017 examined the association between failure to reverse neuromuscular blockade and postoperative pneumonia.[66,67] In an investigation examining 13,100 surgical patients, Bulka and associates observed that the risk of postoperative pneumonia was 2.26 times more likely in patients that did not receive reversal with neostigmine.[66] Similarly, a retrospective study of 11,355 noncardiac patients revealed that the risk of respiratory complications (failure to wean from the ventilator, reintubation, or pneumonia) was significantly higher (odds ratio 1.75) in patients who were administered an NMBD without neostigmine compared to those given neostigmine.[66]

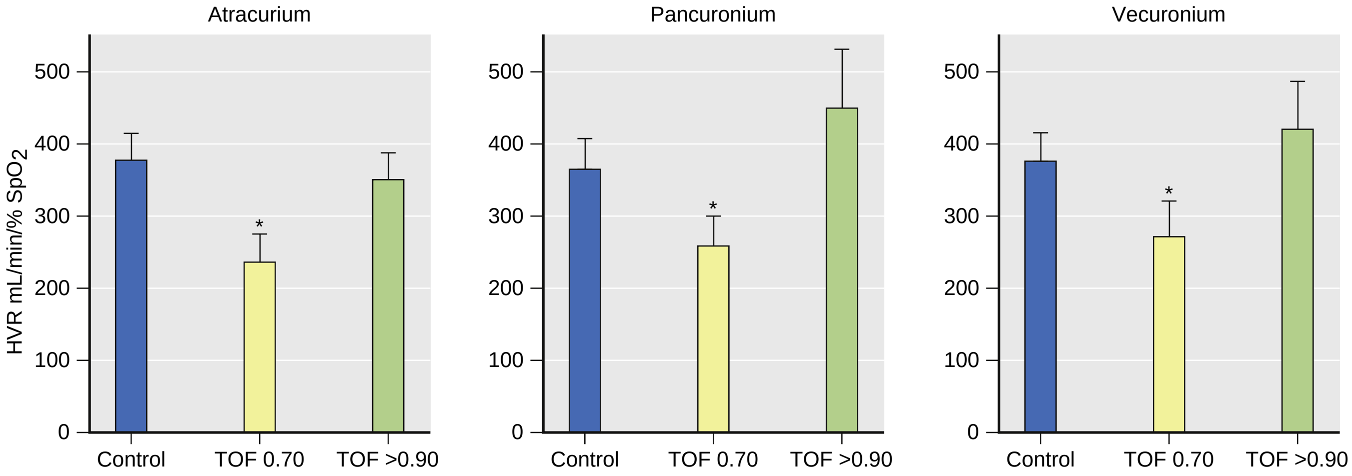

Fig. 28.6 Hypoxic ventilatory response *(HVR)* before (control); during steady-state infusion at train-of-four *(TOF)* ratio 0.70 of atracurium, pancuronium, and vecuronium; and after recovery (TOF ratio > 0.90). Data presented as means ± SD. * = P <.01. SpO_2, Saturation of arterial blood with oxygen. (From Eriksson LI. Reduced hypoxic chemosensitivity in partially paralysed man: a new property of muscle relaxants. *Acta Anaesthesiol Scand.* 1996;40:520–523.)

Epidemiologic studies thus suggest an association between incomplete neuromuscular recovery and adverse events in the early postoperative period. Notably, an important limitation of these outcome studies is that residual paresis was not quantified at the end of surgery. Therefore causality (residual blockade results in postoperative complications) can only be suggested but not proven.

In order to address these limitations, more recent studies have quantified TOF ratios in the PACU and documented a relationship between residual blockade and adverse outcomes. Several clinical investigations have documented an association between postoperative residual blockade and adverse respiratory events. In an observational study by Bissinger and colleagues, patients with TOF ratios less than 0.70 in the PACU had a more frequent incidence of hypoxemia (60%) compared with patients with TOF ratios 0.70 or greater (10%, $P < .05$).[68] Another small study of orthopedic surgical patients randomized to receive either pancuronium or rocuronium revealed that patients with TOF ratios less than 0.90 on arrival to the PACU were more likely to develop postoperative hypoxemia (24 of 39 patients) than those with TOF ratios greater than 0.90 (7 of 30 patients, $P = .003$).[69] Murphy and associates conducted a case-control study examining the incidence and severity of residual blockade in patients who developed critical respiratory events in the PACU.[38] Seventy-four percent of patients in the group with critical respiratory events had TOF ratios less than 0.70, compared with 0% in the matched control group (matched for age, sex, and surgical procedure). Because the two cohorts did not differ in any perioperative characteristics with the exception of neuromuscular recovery, these findings suggest that unrecognized residual paralysis is an important contributing factor to postoperative adverse respiratory events. Another investigation by this same group examined the effect of AMG monitoring on postoperative respiratory events.[26] Few patients randomized to AMG monitoring had postoperative TOF ratios less than 0.90, and a less frequent incidence of early hypoxemia and airway obstruction was observed in this group (compared with patients randomized to standard qualitative monitoring). A study of 114 patients randomized to neostigmine reversal or placebo (saline) documented a significantly more frequent incidence of both postoperative residual blockade and hypoxemia in the placebo group.[70] Residual blockade in the PACU may also result in pulmonary complications within the first postoperative week. Berg and colleagues randomized 691 patients to receive pancuronium, atracurium, or vecuronium.[71] TOF ratios were quantified in the PACU, and subjects were followed for 6 days for pulmonary complications. In the pancuronium group, significantly more patients with TOF ratios less than 0.70 developed a pulmonary complication (16.9%) compared with patients with TOF 0.70 or greater (4.8%). Notably, the study also demonstrated a continuously increased risk for postoperative pulmonary complications with increased age, a finding of significant clinical relevance for older adult patients, a growing part of the surgical patient population. Norton and colleagues assessed recovery characteristics in 202 consecutive patients arriving in the PACU. Thirty percent of patients had TOF ratios greater than 0.9; subjects with residual block had a significantly higher incidence of critical respiratory events, airway obstruction, hypoxemia, and respiratory failure.[72] An observational study enrolling 150 patients ages 18 to 50 and 150 patients more than 70 years old assessed the association between incomplete neuromuscular recovery (TOF < 0.9) and adverse events from the time of tracheal extubation until hospital discharge.[73] Elderly subjects had a higher risk of residual block (58% vs. 30%), and those elderly with TOF ratios less than 0.9 had a significantly higher incidence of airway obstruction episodes and hypoxemic events, as well as signs and symptoms of muscle weakness.[73] A multicenter study from Spain enrolling 763 patients from 26 centers reported that 27% of patients had TOF ratios less than 0.9 and that these subjects had a higher incidence of adverse respiratory events (odds ratio 2.57) and an increased risk of reintubation.[74] An additional study (340 patients) noted that patients with residual block had a greater than sixfold increase in postoperative adverse respiratory events.[75]

Residual blockade causes unpleasant symptoms of muscle weakness. This symptom of “general weakness” was the most sensitive “test” for determining whether patients had a TOF ratio of less than 0.90 in the PACU.[17] Orthopedic surgical patients given pancuronium had a more frequent risk of exhibiting both TOF ratios less than 0.90 and symptoms of blurry vision and general weakness during the PACU admission, compared with patients randomized to receive rocuronium.[69] Similar findings were observed in a cardiac surgical patient population not receiving anticholinesterase drugs.[76] The subjective experience of residual neuromuscular blockade after surgery was determined by examining 155 patients for 16 symptoms of muscle weakness during the PACU admission.[27] The presence of symptoms of muscle weakness was predictive of a TOF ratio less than 0.90 (good sensitivity and specificity).

The residual effects of NMBDs on postoperative muscle strength may impair clinical recovery and prolong PACU discharge times. In a small study of patients randomized to receive either pancuronium or rocuronium, the times required to meet and achieve discharge criteria were significantly longer in the pancuronium group, and patients in the cohort as a whole with postoperative TOF ratios less than 0.90 were more likely to have a prolonged PACU stay compared with those with TOF ratios greater than 0.90.[69] A larger investigation measured TOF ratios in 246 consecutive patients on arrival to the PACU.[39] The PACU length of stay was significantly longer in patients with TOF ratios less than 0.90 (323 minutes) compared with patients with adequate recovery of neuromuscular function (243 minutes). Multiple regression analysis revealed that only age and residual blockade were independently associated with PACU length of stay.

In conclusion, a number of studies conducted over the past five decades have documented the effects of small degrees of residual blockade in human volunteers and surgical patients. Awake volunteer investigations have demonstrated that subjects with TOF ratios less than 0.90 have reduced upper airway tone and diameters, upper airway obstruction, pharyngeal dysfunction with impaired airway integrity, decreased upper esophageal tone, and an increased risk of aspiration, impaired hypoxic ventilatory control, and unpleasant symptoms of muscle weakness. Epidemiologic outcome investigations have suggested an association between incomplete neuromuscular recovery and major morbidity and mortality. Prospective clinical trials have revealed that patients with TOF ratios less than 0.90 in the PACU are at increased risk for hypoxemic events, airway obstruction, postoperative pulmonary complications, symptoms of muscle weakness, and prolonged PACU admission times. These data suggest that residual blockade is an important patient safety issue in the early postoperative period. Therefore appropriate management of reversal of neuromuscular blockade and assessment of recovery from neuromuscular blockade are two essential clinical components to optimize patient outcomes.

Drugs Used to Antagonize (Reverse) Neuromuscular Blockade

Reversal of neuromuscular blockade is theoretically possible by three principal mechanisms: (1) an increase in presynaptic release of acetylcholine; (2) a decrease in enzymatic metabolism of acetylcholine by cholinesterase, thereby increasing receptor binding competition; and (3) a decrease in the concentration of the NMBD at the effect-site, freeing the postsynaptic receptors.

ANTICHOLINESTERASE REVERSAL OF NEUROMUSCULAR BLOCKADE

Nondepolarizing NMBDs inhibit neuromuscular transmission primarily by competitively antagonizing or blocking the effect of acetylcholine at the postjunctional nicotinic acetylcholine receptor (nAChR). Binding of nondepolarizing NMBDs to the nAChR occurs in a competitive fashion. If larger concentrations of acetylcholine are present at the neuromuscular junction, acetylcholine will attach to the postsynaptic receptor and facilitate neuromuscular transmission and muscle contraction. Conversely, if larger concentrations of a nondepolarizing NMBD are present at the neuromuscular junction, binding to α subunits of the receptor will preferentially occur, preventing central pore opening and muscle depolarization from occurring. A more detailed description of the neuromuscular junction is provided in Chapter 12.

One mechanism of reversing the effects of NMBDs is by an increase in the concentration of acetylcholine at the neuromuscular junction. This can be accomplished using an inhibitor of cholinesterase, which constrains the enzyme that breaks down acetylcholine at the neuromuscular junction (acetylcholinesterase). Three anticholinesterase drugs are commonly used in clinical practice: neostigmine, edrophonium, and pyridostigmine. Neostigmine is likely the most commonly administered drug. Over the prior six decades, anticholinesterases have been the only drugs used clinically to reverse neuromuscular blockade (until the recent introduction of sugammadex).

Mechanism of Action of Anticholinesterases

Acetylcholine is the primary neurotransmitter that is synthesized, stored, and released by exocytosis at the distal motor nerve terminal. Acetylcholinesterase is the enzyme responsible for the control of neurotransmission at the neuromuscular junction by hydrolyzing acetylcholine. Rapid hydrolysis of acetylcholine removes excess neurotransmitter from the synapse, preventing overstimulation and tetanic excitation of the postsynaptic muscle. Nearly half of the acetylcholine molecules released from the presynaptic nerve membrane are hydrolyzed by acetylcholinesterase before reaching the nAChR.[77] The action of acetylcholinesterase is quite rapid; acetylcholine molecules are hydrolyzed in approximately 80 to 100 µs (microseconds). Acetylcholinesterase is concentrated at the neuromuscular junction, and there are approximately 10 enzyme-binding sites for each molecule of acetylcholine released.[78] However, lower concentrations of acetylcholinesterase are present along the length of the muscle fiber. Each molecule of acetylcholinesterase has an active surface with two important binding sites, an anionic site and an esteratic site. The negatively charged anionic site on the acetylcholinesterase molecule is responsible for electrostatically binding the positively charged quaternary nitrogen group on the acetylcholine molecule. The esteratic site forms covalent bonds with the carbamate group at the opposite end of the acetylcholine molecule and is responsible for the hydrolytic process (Fig. 28.7).[78] In addition, a secondary or peripheral anionic site has been proposed. Binding of ligands to the peripheral anionic site results in inactivation of the enzyme.

The anticholinesterase drugs used by anesthesiologists interact with the anionic and esteratic sites of acetylcholinesterase. These drugs are characterized as either prosthetic inhibitors (edrophonium) or oxydiaphoretic (acid-transferring) inhibitors (neostigmine, pyridostigmine) of the enzyme. Edrophonium rapidly binds to the anionic site via electrostatic forces and to the esteratic site by hydrogen bonding.[77,78] Rapid binding may account for the short onset of action of edrophonium in clinical practice. During the time edrophonium is bound, the enzyme is inactive and edrophonium is not metabolized. However, the interaction between edrophonium and acetylcholinesterase is weak and short-lived. The dissociation half-life of this interaction is approximately 20 to 30 seconds, and the interaction between drug and enzyme is competitive and reversible. Because the nature of the binding is relatively brief, the efficacy of edrophonium in reversing neuromuscular blockade may be limited. Neostigmine and pyridostigmine are oxydiaphoretic inhibitors of acetylcholinesterase, which also

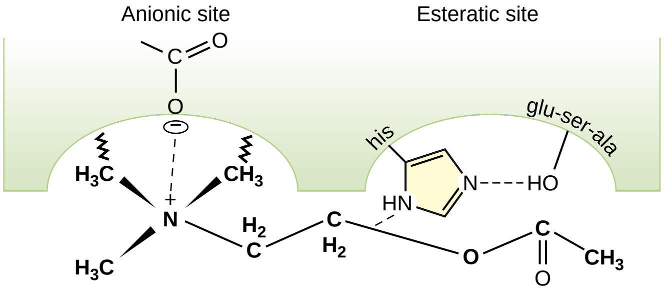

Fig. 28.7 Active binding sites on acetylcholinesterase. The positively charged quaternary nitrogen group on acetylcholine (Ach) binds by electrostatic forces to the negatively charged anionic site on the enzyme. The carbamate group at the opposite end of the Ach molecule forms covalent bonds with and is metabolized at the esteratic site. (From Caldwell JE. Clinical limitations of acetylcholinesterase antagonists. *J Crit Care.* 2009;24:21–28.)

bind to the anionic site. In addition, these drugs transfer a carbamate group to acetylcholinesterase, creating a covalent bond at the esteratic site.[77,78] This reaction results in an inactivation of the enzyme, as well as the hydrolysis of the drug. The stronger interaction between neostigmine and enzyme results in dissociation half-life of approximately 7 minutes.[78] Therefore the duration of enzyme inhibition is longer with neostigmine and pyridostigmine compared with edrophonium. These interactions at the molecular level likely have little impact on the duration of action in clinical practice. Duration of clinical effect is primarily determined by removal of anticholinesterase from the plasma.[79]

The administration of anticholinesterases has also been reported to produce presynaptic effects.[79] Laboratory investigations have demonstrated that these prejunctional effects may actually facilitate neuromuscular transmission. Anticholinesterases produce a reversible increase in the duration of the action potential and refractory period of the nerve terminal. Because the quantity of acetylcholine released is a function of the extent and duration of the depolarization of the terminal membrane, the period of acetylcholine release in response to nerve stimulation may be increased by anticholinesterase agents.[79] Excessive release of acetylcholine, coupled with decreased hydrolysis due to acetylcholinesterase inhibition, results in prolonged endplate potentials and repetitive firing of muscle fibers. These prejunctional effects appear to account for the observations that spontaneous contractions of muscles can occur when anticholinesterases are given in the absence of NMBDs.[79]

Although neostigmine, pyridostigmine, and edrophonium inhibit the breakdown of acetylcholine, resulting in an increase in acetylcholine in the neuromuscular junction, there is a clinically relevant "ceiling" effect to the maximal concentration of acetylcholine. As concentrations of acetylcholine increase, some of the neurotransmitter diffuses away from the neuromuscular junction, while additional acetylcholine undergoes reuptake into motor nerve terminals. As the processes of diffusion and reuptake reach equilibrium with augmented release by enzyme inhibition, a "peak" level at the neuromuscular junction is reached.[78] Once the acetylcholinesterase enzyme is maximally inhibited by an anticholinesterase agent and peak concentrations of acetylcholine are present, the administration of additional drug will not further increase acetylcholine levels or enhance recovery of neuromuscular blockade. This "ceiling" effect of anticholinesterases is an important limitation of all clinically used agents; neuromuscular blockade cannot be adequately reversed if high concentrations of NMBDs are present at the neuromuscular junction.

Pharmacokinetic and Pharmacodynamic Properties of Anticholinesterases

A large number of clinical studies have examined the pharmacokinetic and pharmacodynamic characteristics of neostigmine, pyridostigmine, and edrophonium.

The pharmacokinetic profiles of neostigmine, pyridostigmine, and edrophonium are presented in Table 28.3. Most studies have used a two-compartment model to establish pharmacokinetic characteristics of each agent. Following a bolus administration, plasma concentrations peak rapidly and decline significantly within the first 5 to 10 minutes. This is followed by a slower decline in plasma concentrations due to the elimination phase.[79] In general, the pharmacokinetic profiles of all three anticholinesterases are similar. Early studies suggested that the duration of edrophonium was too short for clinical use. However, studies using larger doses (0.5 or 1.0 mg/kg) demonstrated that the elimination half-life of edrophonium was not significantly different from that of neostigmine or pyridostigmine and that edrophonium could produce prompt and sustained reversal of neuromuscular blockade.[80,81] The longer elimination half-life of pyridostigmine likely accounts for the longer duration of action compared with the other anticholinesterase drugs.[82]

The pharmacokinetics of anticholinesterases can be influenced by renal function, age, and body temperature. The elimination half-life of all three agents is altered by the presence of renal insufficiency or failure (see Table 28.3). Renal excretion accounts for approximately 50% of plasma clearance of neostigmine; elimination half-life is significantly prolonged and serum clearance decreased in anephric patients.[83] Similarly, renal function accounts for 70% to 75% of serum clearance of pyridostigmine and edrophonium.[82,84] The reduced plasma clearance of the anticholinesterases in renal failure patients provides a "margin of safety" against the risk of postoperative "recurarization" (the effects of the NMBD persist longer than that of the reversal agent, resulting in a worsening of residual paresis). The pharmacokinetics of edrophonium have been examined in older adult (age > 70 years) patients. When compared with a younger cohort, older adult patients exhibited a significant decrease in plasma clearance (5.9 ± 2 vs. 12.1 ± 4 mL/kg/min) and a prolonged elimination half-life (84.2 ± 17 vs. 56.6 ± 16 minutes).[85] Mild hypothermia (reduction in core temperature of 2°C) more than doubles the duration of action of intermediate-acting NMBDs.[86] In a study of human volunteers cooled to 34.5°C, the central volume of distribution of neostigmine decreased 38% and the onset time of maximal blockade increased from 4.6 to 5.6 minutes.[87] However, the clearance, maximal effect, and duration of action of neostigmine were not altered by a reduction in body temperature. Therefore if hypothermia influences the degree of neuromuscular recovery, it is likely

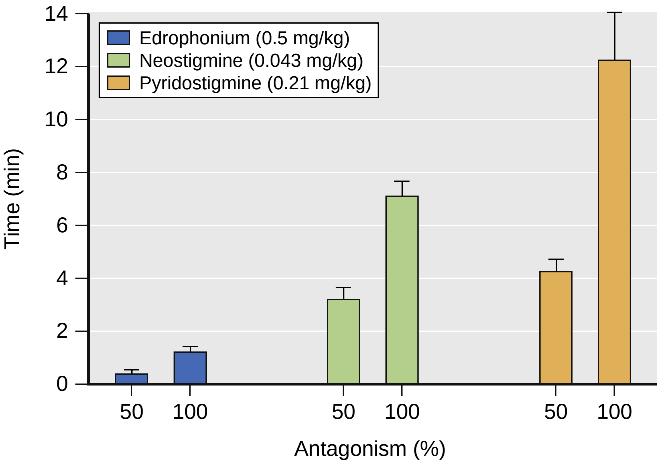

Fig. 28.8 Comparison of onset of action for edrophonium, neostigmine, and pyridostigmine. Values plotted are means ± SE. Edrophonium's onset was significantly faster than neostigmine or pyridostigmine. (From Cronnelly R, Morris RB, Miller RD. Edrophonium: duration of action and atropine requirement in humans during halothane anesthesia. *Anesthesiology*. 1982;57:261–266.)

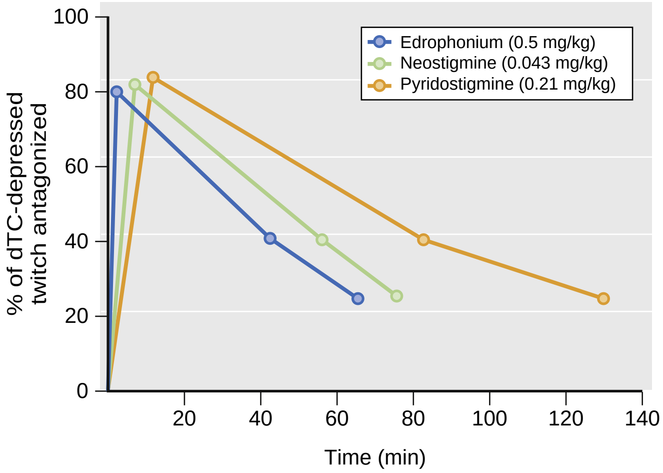

Fig. 28.9 Duration of antagonism compared at equipotent doses of neostigmine, pyridostigmine, and edrophonium. Values plotted are means. Edrophonium did not differ from neostigmine in duration; however, both were shorter than pyridostigmine. *dTC,* d-tubocurarine. (From Cronnelly R, Morris RB, Miller RD. Edrophonium: duration of action and atropine requirement in humans during halothane anesthesia. *Anesthesiology*. 1982;57:261–266.)

secondary to an effect on the pharmacology of NMBDs (not the anticholinesterase).

Onset of action may be more rapid with edrophonium than with either neostigmine or pyridostigmine. When *d*-tubocurarine neuromuscular blockade was reversed with approximately equipotent doses of the three clinically used anticholinesterases, the peak effect of antagonism was reached significantly faster with edrophonium (0.8-2.0 minutes) than with neostigmine (7-11 minutes) or pyridostigmine (12-16 minutes) (Fig. 28.8).[80] Similar findings have been observed in patients receiving other long- and intermediate-acting NMBDs. When larger doses (0.5-1.0 mg/kg) of edrophonium are administered during moderate levels of neuromuscular blockade (10% recovery of single-twitch height after pancuronium or atracurium), the onset time of edrophonium was faster than neostigmine.[88,89] During deeper levels of blockade (<10% recovery of single twitch), edrophonium 1.0 mg/kg and neostigmine 0.04 mg/kg had similar onset times when vecuronium was used (and both were faster than edrophonium 0.5 mg/kg).[90] When pancuronium was antagonized during deep blockade, edrophonium 1.0 mg/kg had a shorter onset time than neostigmine 0.04 mg/kg.[90] These findings suggest that onset time of antagonism is influenced by the type and dose of anticholinesterase used, the choice of NMBD administered intraoperatively, and the depth of neuromuscular blockade at the time of antagonism.

The duration of action of anticholinesterases is determined not only by the pharmacokinetic properties of the drugs, but also by the concentration of NMBD present at the neuromuscular junction at the time of reversal. Duration of neuromuscular blockade will naturally decrease over time as a result of metabolism and elimination of NMBDs. To accurately assess the duration of action of anticholinesterases during a stable, constant level of neuromuscular blockade, investigators have administered these agents to patients receiving an infusion of *d*-tubocurarine titrated to a 90% depression of single-twitch height.[80] The investigators observed that the duration of action of equipotent doses of neostigmine (0.043 mg/kg) and edrophonium (0.5 mg/kg) were similar (Fig. 28.9). The duration of both drugs, however, was significantly less than with pyridostigmine (0.21 mg/kg).

The comparative potencies of clinically used anticholinesterases have been calculated by constructing dose-response curves. In general, neostigmine is more potent than pyridostigmine, which is more potent than edrophonium. Neostigmine-to-pyridostigmine potency ratios of 4.4 to 6.7 have been reported (neostigmine is 4.4-6.7 times more potent than pyridostigmine).[80,91] Neostigmine is even more potent than edrophonium, with potency ratios of 5.7 to 19.5 estimated from dose-response curves.[80,91,92] The great variability in potency ratios described in the literature is related to several factors, which include the type of NMBD used in the studies, the endpoint selected to represent neuromuscular recovery, and the depth of blockade at the time of anticholinesterase administration.

In conclusion, pharmacokinetic and pharmacodynamic studies suggest that neostigmine, pyridostigmine, and edrophonium are all effective in reversing neuromuscular blockade when used in appropriate and equipotent doses. The following section will review factors that determine the efficacy of these agents in reversing neuromuscular blockade in the clinical setting.

Factors Determining the Adequacy of Recovery Following Administration of Anticholinesterases

Depth of Neuromuscular Blockade or Train-of-Four Count at the Time of Reversal. The primary anesthetic management variable determining the effectiveness of anticholinesterase agents in completely antagonizing neuromuscular blockade at the end of surgery is the depth of neuromuscular blockade at the time of reversal. As opposed to sugammadex (see later in this chapter), reversal of blockade by anticholinesterases should not be attempted until some evidence of spontaneous recovery is present. Kirkegaard-Nielsen and associates examined the optimal time for

TABLE 28.4 Time (min) from Neostigmine Administration to a Train-of-Four Ratio 0.70, 0.80, and 0.90 When Given at a Train-of-Four Count of 1-4

neostigmine reversal of an atracurium blockade.[93] Administration of neostigmine 0.07 mg/kg during deep blockade (before the first twitch height reached 8%) resulted in significant prolongation of reversal times. In a similar investigation, atracurium was antagonized with neostigmine during intense blockade (posttetanic count [PTC] of 1 to >13).[94] Early administration of neostigmine did not shorten total recovery time and offered no clinical advantages. Similar findings have been observed during reversal of deep vecuronium blockade.[95] The total time to achieve a TOF ratio of 0.75 was the same whether neostigmine (0.07 mg/kg) was given 15 minutes after an intubating dose of vecuronium or whether single-twitch height had recovered to 10% of control.

The time required to achieve a TOF ratio of 0.90 after anticholinesterase administration is significantly shorter when a higher TOF count is present at reversal. Two studies have examined the efficacy of antagonizing residual blockade at varying TOF counts. Kirkegaard and colleagues randomized patients receiving cisatracurium to reversal with neostigmine (0.07 mg/kg) at the reappearance of the first, second, third, and fourth tactile TOF response (TOF count 1-4).[96] The median (range) time required to achieve a TOF ratio of 0.90 was 22.2 (13.9-44.0) minutes when reversal was attempted at a TOF count of 1. However, even when four responses were present, the time needed to attain a TOF ratio of 0.90 was 16.5 (6.5-143.3) minutes (Table 28.4). Kim and associates performed a similar study in which patients administered rocuronium were randomized to be reversed at the first through fourth tactile TOF responses.[97] In those patients receiving sevoflurane for anesthetic maintenance, the median (range) time required to achieve a TOF ratio of 0.90 was 28.6 (8.8-75.8) minutes when reversed at a TOF count of 1 and 9.7 (5.1-26.4) minutes when reversed at a TOF count of 4. In both investigations, a large interindividual variability in reversal times was observed.[96,97] This is likely a reflection of the individual response to the NMBD administered. The reason for marked prolongation of reversal times in some patients (up to 143 minutes) was not determined, but may be due to the "ceiling effect" with respect to the blockade (peak effect of the antagonist is followed by a plateau phase in which the balance between diminishing anticholinesterase activity and spontaneous recovery determines the slope of the recovery curve).[96] Both studies demonstrated that it was not possible to reliably achieve full neuromuscular recovery (TOF ratio of >0.90) in the majority of patients within 10 minutes of anticholinesterase administration. On the basis of data, expert opinion suggests that neostigmine should not be administered until the fourth "twitch" of the TOF count has returned.[98]

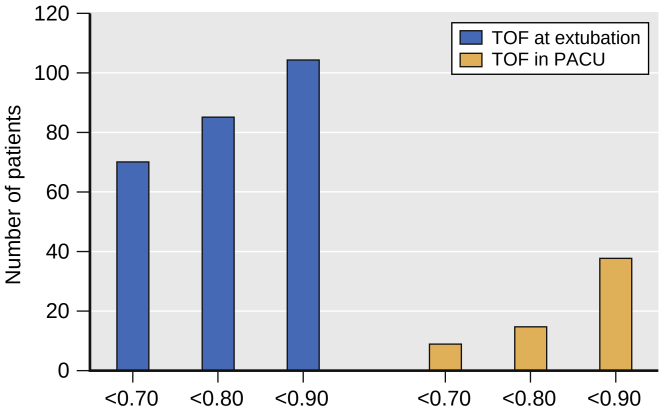

Fig. 28.10 Train-of-four (TOF) ratios measured immediately before tracheal extubation and again on admission to the postanesthesia care unit *(PACU)*. The graphs illustrate the number of patients (of a total of 120) with TOF ratios <0.70, <0.80, and <0.90 at each measurement interval. (From Murphy GS, Szokol JW, Marymont JH, et al. Residual paralysis at the time of tracheal extubation. *Anesth Analg.* 2005;100:1840–1845.)

Time Interval Between Anticholinesterase Administration and Tracheal Extubation. Studies have suggested that if four responses to TOF nerve stimulation are present, approximately 15 minutes are needed to reach a TOF ratio of 0.90 in most patients.[96,97] Achieving a TOF ratio of 0.90 will require a significantly longer time (20–30 minutes) if a TOF count of 1 to 3 is observed at the time of reversal. To allow adequate neuromuscular recovery and ensure patient safety, anticholinesterase drugs should be given, on average, 15 to 30 minutes before clinicians anticipate removal of the endotracheal tube in the operating room. In many clinical situations, however, anticholinesterases are often administered at the conclusion of surgical closure, with tracheal extubation performed shortly thereafter. A survey of anesthesiologists from Europe and the United States revealed that approximately one half of respondents allowed only 5 minutes or less between anticholinesterase administration and tracheal extubation.[11] In a study of 120 surgical patients, TOF ratios were quantified at the time of tracheal extubation when clinicians had determined that full recovery of neuromuscular function had occurred using clinical criteria and qualitative neuromuscular monitoring (Fig. 28.10).[73] Mean TOF ratios of 0.67 were observed immediately before extubation, with

88% of patients exhibiting TOF less than 0.90. Of note, the median TOF count at reversal was 4, and the average time interval between neostigmine administration and tracheal extubation was only 8 minutes. The frequent incidence of residual blockade reported in multiple studies is likely attributable to the fact that anticholinesterases are not given early enough during the intraoperative anesthetic to ensure full neuromuscular recovery.

Type of Neuromuscular Blocking Drug Used Intraoperatively (Long-Acting Versus Intermediate-Acting). Two separate processes contribute to recovery of neuromuscular function following anticholinesterase administration. The first is the inhibition of acetylcholinesterase at the neuromuscular junction produced by neostigmine, pyridostigmine, or edrophonium. The second is the spontaneous process of decrease in the concentration of the NMBD at the neuromuscular junction over time due to redistribution and elimination. Therefore NMBDs that are redistributed and eliminated more rapidly from the plasma should be associated with more rapid recovery profiles after anticholinesterase use. Not surprisingly, the probability of satisfactorily antagonizing neuromuscular blockade is a function of the properties of the NMBD used to provide muscle relaxation. The ability of edrophonium (0.75 mg/kg) and neostigmine (0.05 mg/kg) to antagonize neuromuscular blockade produced by atracurium, vecuronium, and pancuronium following termination of steady-state infusions (single-twitch depression 10% of control) has been examined.[99] TOF ratios 20 minutes postreversal were 0.80 and 0.95 (atracurium with edrophonium or neostigmine), 0.76 and 0.89 (vecuronium with edrophonium or neostigmine), and 0.44 and 0.68 (pancuronium with edrophonium or neostigmine). Another clinical study investigated recovery of neuromuscular function in patients randomized to receive either intermediate-acting (rocuronium, vecuronium, atracurium) or long-acting (pancuronium) NMBDs.[100] Neostigmine (0.04 mg/kg) was given at 25% recovery of control twitch height, and TOF ratios were measured for 15 minutes. Mean TOF ratios had recovered to 0.88 to 0.92 in patients receiving intermediate-acting NMBDs, versus only 0.76 in the pancuronium group (Fig. 28.11).

A number of clinical investigations have examined the incidence of residual blockade in the PACU in patients receiving either intermediate- or long-acting NMBDs. These studies have consistently demonstrated that fewer patients given intermediate-acting NMBD have residual blockade compared with those receiving long-acting agents. A meta-analysis of 24 clinical trials examined the pooled estimated incidence of residual blockade (defined as a TOF ratio <0.90) by muscle relaxant type.[44] The risk of residual blockade was significantly less in patients given intermediate-acting NMBDs (41%) versus long-acting NMBDs (72%). In conclusion, the probability of incomplete neuromuscular recovery in the early postoperative period is decreased when shorter-acting NMBDs are used intraoperatively.

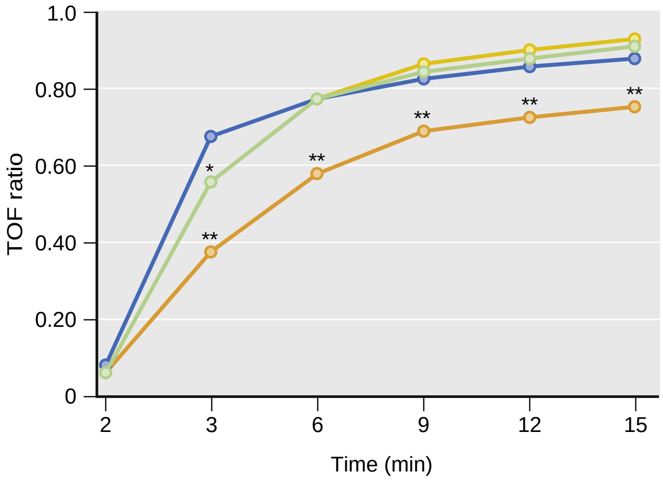

Fig. 28.11 Evolution of the train-of-four *(TOF)* ratio (mean) recorded at 3-minute intervals after administration of neostigmine 40 µg/kg when twitch height had returned to 25% of its initial value in groups of Roc *(green)*, Vec *(blue)*, Atr *(yellow)*, and Pan *(orange)*. *$P < .05$, one-way analysis of variance and Duncan multiple classification range tests (group Vec vs. groups Roc and Atr). **$P < .01$, one-way analysis of variance and Duncan multiple classification range tests (group Pan versus groups Vec, Roc, Atr). (From Baurain MJ, Hoton F, D'Hollander AA, et al. Is recovery of neuromuscular transmission complete after the use of neostigmine to antagonize block produced by rocuronium, vecuronium, atracurium and pancuronium? *Br J Anaesth.* 1996;77:496–499.)

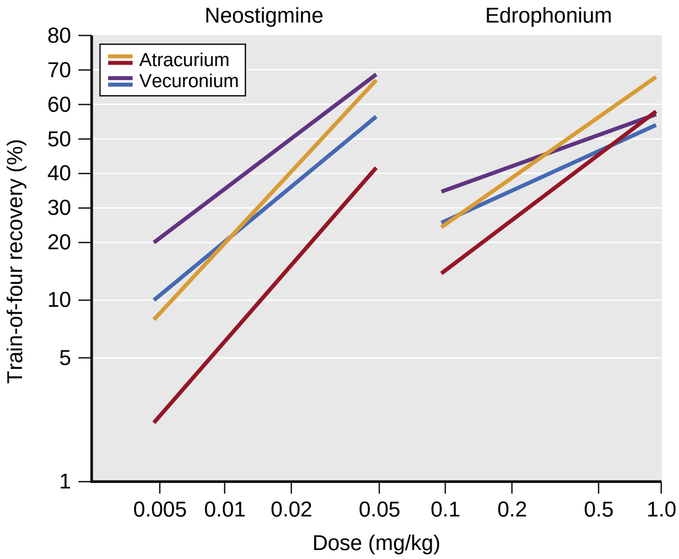

Fig. 28.12 Dose-response relationships of train-of-four assisted recovery evaluated 5 minutes (blue lines) or 10 minutes (purple lines) after administration of the antagonist as a function of the dose of neostigmine or edrophonium. The slopes of the curves obtained with edrophonium were usually flatter than the corresponding curves for neostigmine. (From Smith CE, Donati F, Bevan DR. Dose-response relationships for edrophonium and neostigmine as antagonists of atracurium and vecuronium neuromuscular blockade. *Anesthesiology.* 1989;71:37–43.)

Type and Dose of Anticholinesterase. Complete recovery of neuromuscular function within 10 to 15 minutes with neostigmine, edrophonium, or pyridostigmine is difficult to achieve when profound neuromuscular blockade is present. Some investigations have suggested that edrophonium is less effective than neostigmine when reversing deep blockade; this may occur because the slopes of the dose-response relationships of neostigmine and edrophonium are not parallel (flatter dose-response curves are observed with edrophonium; Fig. 28.12).[90,92] In contrast, the recovery profile of edrophonium with larger doses (approximately 1.0 mg/kg) does not differ from neostigmine and pyridostigmine, and edrophonium can produce rapid and sustained reversal of neuromuscular blockade.[88,90] At moderate levels of neuromuscular blockade all three agents appear to be similarly effective in reversing blockade, although the onset of edrophonium may occur more quickly.

In general, larger doses of anticholinesterases result in more rapid and complete reversal of neuromuscular blockade than smaller doses. This relationship remains true until the maximal dose of anticholinesterase has been administered. At this point, acetylcholinesterase is maximally inhibited, and additional amounts of anticholinesterase will result in no further antagonism. Maximal effective doses of neostigmine and edrophonium have not been clearly defined, but likely vary in relation to depth of blockade and type of NMBD used intraoperatively. Providing additional anticholinesterase beyond these maximum dose limits (neostigmine 60-80 μg/kg, edrophonium 1.0-1.5 mg/kg) provides no further benefit. When administered during deep neuromuscular blockade, a second dose of neostigmine (70 μg/kg) usually does not enhance recovery times beyond that observed with a single dose.[95]

AGE

INFANTS AND CHILDREN. The dose of neostigmine producing 50% antagonism of a *d*-tubocurarine neuromuscular blockade was slightly smaller in infants (13 μg/kg) and children (15 μg/kg) compared with adults (23 μg/kg).[101] The times to peak antagonism and duration of antagonism did not differ between infants, children, and adults. Pharmacokinetic modeling revealed that distribution half-lives and volumes were similar in all three cohorts, although elimination half-life was shorter in infants and children than adults. As in adults, the depth of neuromuscular blockade at the time of antagonism was a primary factor determining adequacy of recovery.[102,103] Spontaneous recovery from neuromuscular blockade is more rapid in children compared with adults.[103] However, when neostigmine was administered at various levels of blockade, the times to achieve neuromuscular recovery were similar in children and adults (the times to reach a TOF ratio of 0.90 were reduced by 30%–40% compared with spontaneous recovery).[103] Thus in the clinical setting, reversal of neuromuscular blockade does not appear to differ significantly between children and adults.

OLDER ADULTS. Physiologic changes occur during the aging process that result in alterations in the response of older patients to NMBDs. These changes include an increase in body fat, a decrease in total body water, and declines in cardiac, hepatic, and renal function. In addition, anatomic alterations occur at the neuromuscular junction in older adults, such as a decrease in the concentration of nAChRs at the motor end plate and a reduction in the release of acetylcholine from the preterminal axon. All of these factors contribute to a prolongation of effect of most NMBDs in older patients. In a study comparing older adults (age > 70) to younger controls, plasma clearance of edrophonium was decreased and elimination half-life prolonged in the aged cohort. Despite higher plasma concentrations of edrophonium, however, duration of antagonism was not increased. In contrast, Young and colleagues observed that the duration of action of both neostigmine and pyridostigmine was significantly longer in older adults (age > 60) compared with younger subjects.[104] These findings suggest that plasma concentrations and/or duration of action of both NMBDs and anticholinesterases (neostigmine and pyridostigmine) are prolonged in older patients, which should reduce the risk of recurarization. The risk of postoperative residual block in elderly patients (age > 70 years) who have received neostigmine is significantly higher than in a younger cohort receiving similar doses of this drug (ages 18–50, 58% vs. 30%, respectively).[73]

TYPE OF ANESTHESIA. Volatile anesthetics intensify the action of nondepolarizing NMBDs when compared with intravenous anesthetics. Furthermore, volatile anesthetics interfere with the antagonism of neuromuscular blockade.[105] Kim and colleagues randomized patients to receive a propofol or sevoflurane anesthetic (Table 28.5).[97] The times required to achieve a TOF ratio of 0.70, 0.80, and 0.90 were significantly longer in patients given the sevoflurane-based anesthetic compared with the propofol-based technique. Similar findings have been observed in patients randomized to receive either isoflurane or propofol (neuromuscular recovery was delayed when a volatile anesthetic was used).[105,106] These findings suggest that the probability of achieving a TOF ratio greater than 0.90 within 10 to 15 minutes of anticholinesterase administration is increased if a total intravenous anesthetic technique is administered as opposed to a volatile anesthetic.

CONTINUOUS INFUSION VERSUS BOLUS ADMINISTRATION OF NEUROMUSCULAR BLOCKING DRUGS. Recovery from neuromuscular blockade may also be influenced by mode of NMBD administration. Jellish and colleagues examined recovery characteristics of rocuronium and cisatracurium when given as either a bolus or continuous infusion.[106] The time required to reach a TOF ratio of 0.75 in the cisatracurium group was similar whether bolus or infusion techniques were used, whereas recovery was delayed when rocuronium was given as an infusion.[106] The authors conclude that cisatracurium may be the agent of choice for prolonged procedures since its recovery is not affected by length of infusion.

RENAL FUNCTION. As previously noted, renal excretion accounts for 50% to 75% of plasma clearance of neostigmine, pyridostigmine, and edrophonium. In anephric patients, elimination half-life of all three anticholinesterases is prolonged, and total plasma clearance of these agents is decreased (see Table 28.3). Similar changes in the pharmacokinetic characteristics of nondepolarizing NMBDs have been noted in patients with renal failure. Therefore management of anticholinesterase reversal should be similar in patients with normal and impaired renal function. Postoperative residual neuromuscular blockade in patients with renal failure is more likely secondary to improper titration of NMBDs intraoperatively rather than to inappropriate dosing of anticholinesterase agents.

ACID-BASE STATUS. The influence of metabolic status and respiratory acid-base balance on reversal of neuromuscular blockade has been investigated in the laboratory setting. Miller and associates noted that respiratory alkalosis and metabolic acidosis did not alter the dose of neostigmine needed to reverse a *d*-tubocurarine or pancuronium blockade. However, during respiratory acidosis and metabolic alkalosis, the dose of neostigmine needed to produce a comparable level of neuromuscular recovery was nearly twice

From Kim KS, Cheong MA, Lee HJ, Lee JM. Tactile assessment for the reversibility of rocuronium-induced neuromuscular blockade during propofol or sevoflurane anesthesia. *Anesth Analg*. 2004;99:1080–1085.

as large.[107,108] Although clinical studies have not been performed, the findings from laboratory investigations suggest that complete reversal of neuromuscular blockade may be difficult in the presence of respiratory acidosis and metabolic alkalosis. In particular, clinicians should be aware of the risk of residual blockade in the setting of respiratory acidosis. A number of anesthetics (opioids, benzodiazepines, volatile anesthetics) can potentially depress the ventilatory drive in the early postoperative period. This respiratory depression may result in respiratory acidosis, which limits the ability of anticholinesterases to reverse neuromuscular blockade. The resultant residual blockade may further depress the respiratory muscle strength and ventilatory drive and increase the risk of adverse postoperative events.

Neuromuscular Monitoring. Qualitative and quantitative neuromuscular monitoring should be used to guide dosing of both NMBDs and their reversal in the operating room. In general, if deeper levels of neuromuscular blockade are present at the end of surgery (1-2 responses to TOF stimulation), larger doses of anticholinesterases should be given. In these clinical scenarios, maximal doses of neostigmine (70 μg/kg), edrophonium (1.0-1.5 mg/kg), or pyridostigmine (350 μg/kg) should be considered. If three to four responses to TOF stimulation are present with observable fade of the fourth response, moderate doses of anticholinesterase should be administered (40-50 μg/kg of neostigmine, 0.5 mg/kg of edrophonium, 200 μg/kg pyridostigmine). If four responses are present with no fade, low doses of anticholinesterases can be considered (e.g., 20 μg/kg of neostigmine; see later).

Quantitative monitoring is also useful in guiding the dosing of anticholinesterases. Fuchs-Buder and colleagues investigated the dose-response relationship of neostigmine using AMG-based monitoring to guide neostigmine reversal (10, 20, or 30 μg/kg) given at TOF ratios of either 0.40 or 0.60 (Fig. 28.13).[109] All patients were able to achieve a TOF ratio of 0.90 within 10 minutes of receiving 20 μg/kg of neostigmine. These findings demonstrate that small doses of neostigmine can be safely used if neuromuscular recovery is measured with quantitative monitoring. If muscle function is monitored manually with a peripheral nerve stimulator and no fade is detected manually with TOF stimulation, the TOF ratio is likely at least 0.40, but may be as high as 0.90 or 1.0. In the setting of full neuromuscular recovery, neostigmine administration may produce paradoxical muscle weakness (see later). This potential risk should be considered if neostigmine is used to reverse shallow blockade based on the results of qualitative neuromuscular monitoring.

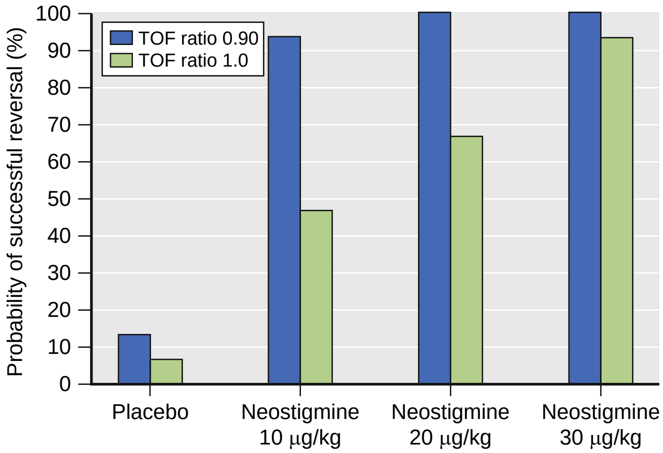

Fig. 28.13 Probability of successful reversal within 10 minutes after different doses of neostigmine or placebo. Neostigmine or placebo was given at a train-of-four ratio of 0.40. *TOF*, Train-of-four. (From Fuchs-Buder T, Meistelman C, Alla F, et al. Antagonism of low degrees of atracurium-induced neuromuscular blockade: dose-effect relationship for neostigmine. *Anesthesiology*. 2010;112:34–40.)

In many clinical settings neuromuscular monitoring is unfortunately not used and decisions relating to the

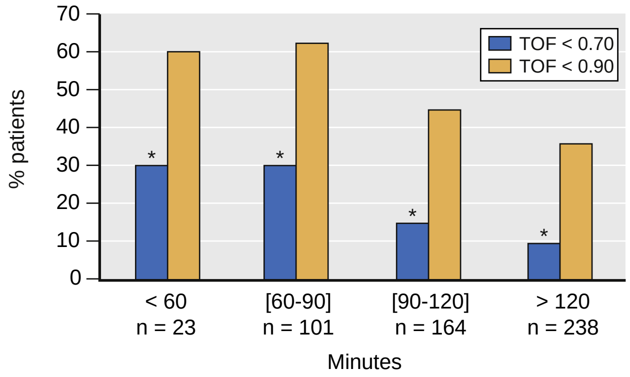

Fig. 28.14 The incidence of residual neuromuscular blockade after a single intubating dose of intermediate-duration nondepolarizing relaxant (rocuronium, vecuronium, or atracurium). Partial paralysis rate (percent) according to the delay between the administration of muscle relaxant and the arrival in the postanesthesia care unit. Partial paralysis was defined as a train-of-four *(TOF)* ratio less than 0.70 or less than 0.90. *n,* number of patients. *Significantly different from TOF < 0.90. (From Debaene B, Plaud B, Dilly MP, Donati F. Residual paralysis in the PACU after a single intubating dose of nondepolarizing muscle relaxant with an intermediate duration of action. *Anesthesiology.* 2003;98:1042–1048.)

administration of anticholinesterases are based on the time that has elapsed between the last dose of NMBD and the conclusion of the anesthetic. Clinical studies do not support this practice. In a study of patients receiving a single intubating dose of vecuronium (0.1 mg/kg), 8.4% of patients had TOF ratios less than 0.80 4 hours after NMBD administration.[110] Debaene and colleagues examined the incidence of residual blockade in a large cohort of patients given a single intubating dose of vecuronium, rocuronium, or atracurium.[47] Of the 239 patients who were tested 2 or more hours after administration of the NMBD, 37% had a TOF ratio less than 0.90 (Fig. 28.14). Murphy and associates administered a single 1 × ED 95 dose of rocuronium (average dose 25 mg) to 120 patients.[111] Despite an average case duration of 161 minutes, 21% of patients had not achieved a TOF ratio of 0.90 at the end of surgery. These investigations, as well as a number of pharmacokinetic and pharmacodynamic studies, demonstrate that the time course of spontaneous neuromuscular recovery is extremely variable from patient to patient. In order to detect and appropriately manage patients in whom delayed neuromuscular recovery may be present, quantitative neuromuscular monitoring is required.

PATIENTS WITH CHOLINESTERASE DEFICIENCY. The duration of neuromuscular blockade following the administration of either succinylcholine or mivacurium is primarily determined by their rate of hydrolysis by plasma cholinesterase. Patients with abnormal plasma cholinesterase phenotypes and activity can demonstrate significant prolongation of clinical effect of these NMBDs. Mivacurium is four to five times more potent in patients phenotypically homozygous for the atypical plasma cholinesterase gene than in patients with normal cholinesterase activity.[112] Following standard intubating doses of mivacurium, recovery of neuromuscular function may require up to 4 to 8 hours in patients with cholinesterase deficiency.[113] Similar prolonged recovery times have been observed in patients administered succinylcholine who have atypical plasma cholinesterase genes.[114]

Human plasma cholinesterase has been used clinically to reverse neuromuscular blockade in patients with atypical serum cholinesterase. In 1977, Scholler and associates reported data on 15 patients with unexpected prolonged apnea lasting several hours after a dose of succinylcholine.[115] Adequate spontaneous ventilation was restored within an average time of 10 minutes in all subjects following the administration of human serum cholinesterase. Naguib and associates reported successful reversal of a profound mivacurium-induced neuromuscular blockade with three doses of a purified human plasma cholinesterase preparation and, in a subsequent study, established a dose-response relationship for plasma cholinesterase as a reversal agent for mivacurium in normal subjects.[113,116] The efficacy of exogenously administered plasma cholinesterase in antagonism of a mivacurium neuromuscular blockade was assessed in 11 patients phenotypically homozygous for atypical plasma cholinesterase.[117] A purified concentrate of cholinesterase (2.8-10 mg/kg) was administered 30 or 120 minutes after an intubating dose of mivacurium. Administration of cholinesterase restored plasma cholinesterase to normal levels, resulting in a 9- to 15-fold increased clearance and a shorter elimination half-life of mivacurium. The first response to TOF stimulation was observed in 13.5 minutes, and the time to achieve a TOF ratio of 0.80 ranged from 30 to 60 minutes. These data suggest that prolonged neuromuscular blockade secondary to low or abnormal plasma cholinesterase activity can be successfully managed with purified human plasma cholinesterase. Decisions relating to management of prolonged neuromuscular blockade in patients with atypical plasma cholinesterase should be based on the availability and cost of human plasma cholinesterase versus delaying tracheal extubation until spontaneous neuromuscular recovery has occurred.

Box 28.2 summarizes clinical management strategies that can be used by clinicians to reduce the risk of residual blockade when NMBDs are antagonized with anticholinesterases.

Complications Associated With Inhibitors of Acetylcholinesterase

ANTICHOLINESTERASE-ASSOCIATED MUSCLE WEAKNESS. Anticholinesterases can antagonize moderate to shallow levels of neuromuscular blockade. However, if given when neuromuscular function is completely recovered, paradoxical muscle weakness theoretically may be induced. Large doses of neostigmine, pyridostigmine, and edrophonium may result in cholinergic hyperactivity and more intense fade in response to multiple nerve stimuli (decrease in TOF ratio) in an in vitro model.[118] The administration of a second dose of neostigmine (2.5 mg) to patients with small degrees of residual blockade resulted in a decrease in TOF ratios, tetanic height, and tetanic fade.[119,120] Caldwell examined neostigmine reversal (20 or 40 μg/kg) of residual neuromuscular blockade 1 to 4 hours after a single dose of vecuronium.[110] TOF ratios increased in 52 patients and decreased in 8 patients; TOF ratio decreases were only observed in patients with TOF ratios 0.90 or greater at the time of reversal (with 40 μg/kg doses of neostigmine but not 20 μg/kg dosing).

The clinical implications of administration of neostigmine after neuromuscular recovery has occurred have been

BOX 28.2 Clinical Management Strategies to Reduce the Risk of Residual Neuromuscular Blockade When Anticholinesterase Reversal Agents Are Used

Quantitative Monitoring Used (e.g., Acceleromyography)

1. TOF count of 1 or no TOF response—delay reversal until neuromuscular recovery is more complete (TOF count of 2 or greater).
2. TOF count of 2 or 3—administer doses of anticholinesterases (neostigmine [70 μg/kg], edrophonium [1.0–1.5 mg/kg], or pyridostigmine [350 μg/kg]). Extubate when the adductor pollicis TOF ratio has reached 0.90.
3. TOF ratio ≥ 0.40—administer moderate pharmacologic reversal doses of anticholinesterases (neostigmine [40–50 μg/kg], edrophonium [0.5 mg/kg], or pyridostigmine [200 μg/kg]). Extubate when the adductor pollicis TOF ratio has reached 0.90.
4. TOF ratio between 0.40 and 0.70—administer pharmacologic reversal, consider a low dose of neostigmine (20 μg/kg).
5. TOF ratio > 0.70—avoid anticholinesterase reversal; risk of anticholinesterase-induced muscle weakness if given.

Qualitative Monitoring Used (Peripheral Nerve Stimulator)

1. TOF count of 1 or no TOF response—delay reversal until neuromuscular recovery is detectable (TOF count of 2 or greater)
2. TOF count of 2 or 3 at the end of surgery—administer anticholinesterases (neostigmine [70 μg/kg], edrophonium [1.0–1.5 mg/kg], or pyridostigmine [350 μg/kg]). Allow at least 15-30 minutes before tracheal extubation is performed.
3. TOF count of 4 with observable fade at the end of surgery (likely adductor pollicis TOF ratio < 0.40)—administer anticholinesterases (neostigmine [40–50 μg/kg], edrophonium [0.5 mg/kg], or pyridostigmine [200 μg/kg]). Allow at least 10–15 minutes before tracheal extubation is performed.
4. TOF count of 4 with no perceived fade at the end of surgery (likely adductor pollicis TOF ratio ≥ 0.40)—administer pharmacologic reversal, consider a low dose of neostigmine (20 μg/kg).

No Neuromuscular Monitoring Used

1. Anticholinesterases should be considered. Spontaneous recovery of neuromuscular function may require several hours in a significant percentage of patients, even after a single intubating dose of an intermediate-acting NMBD.
2. Anticholinesterases should not be given until some evidence of recovery of muscle strength is observed since administration of an anticholinesterase during deep levels of paralysis may delay neuromuscular recovery.
3. Decisions relating to the use or avoidance of anticholinesterases should not be based upon clinical tests of muscle strength (5-second head lift). Many patients can perform these tests even in the presence of profound neuromuscular blockade (TOF ratio < 0.50). Other muscle groups may be significantly impaired (pharyngeal muscles) at the time when patients can successfully perform these tests.

NMBD, Neuromuscular blocking drug; *TOF*, train-of-four.

Modified from Brull SJ, Murphy GS. Residual neuromuscular block. Lessons unlearned. Part II: methods to reduce the risk of residual weakness. *Anesth Analg*. 2010;111:129–140.

examined in studies by Eikermann and colleagues. Rats were administered neostigmine after TOF ratios recovered to 1.0. Neostigmine administration resulted in decreases in upper airway dilator muscle tone and volume, impairment of diaphragmatic function, and reductions in minute ventilation.[121,122] In healthy volunteers given rocuronium, the administration of neostigmine after the recovery of the TOF to 1.0 induced genioglossus muscle impairment and increased upper airway collapsibility.[123] The adverse physiologic effects of neostigmine in the setting of complete neuromuscular recovery can potentially have negative respiratory consequences in postoperative surgical patients. The mechanisms proposed for this effect include sensitivity of the upper airway muscles to an overabundance of acetylcholine with desensitization of the ACh receptor, depolarizing blockade, or an open channel blockade. In contrast, Murphy and colleagues randomized 90 surgical patients to receive either 40 μg/kg of neostigmine or saline when TOF ratio of 0.90 to 1.0 was achieved at the end of surgery.[111] No decreases in TOF ratios were observed in any subjects given neostigmine, and no differences between groups were observed in the incidences of airway obstruction, hypoxemic events, or signs and symptoms of muscle weakness. Studies suggest that sugammadex does not appear to produce adverse effects on upper airway tone or normal breathing when given after neuromuscular recovery.[121]

NAUSEA AND VOMITING. The impact of anticholinesterases on the incidence of postoperative nausea and vomiting remains controversial. Systemic anticholinesterases produce effects outside of the neuromuscular junction that may influence the risk of unwanted side effects following anesthesia and surgery. In addition to the action within the neuromuscular junction, anticholinesterase drugs result in muscarinic effects on the gastrointestinal tract, resulting in stimulation of secretion of gastric fluid and increases in gastric motility. The use of smaller doses of neostigmine in combination with atropine decreases lower esophageal sphincter tone.[124] Furthermore, neostigmine may produce nausea and vomiting via a central effect. Intrathecal neostigmine increases the incidence of nausea and vomiting, likely through a direct effect on the brainstem.

Anticholinergic drugs (e.g., atropine, glycopyrrolate) are routinely administered with anticholinesterases in order to attenuate the undesirable muscarinic effects of these reversal agents. Perhaps anticholinergic drugs have antiemetic properties.[125] When given to children receiving sedation (in the absence of anticholinesterases), atropine was associated with significantly less vomiting (5.3%) than either glycopyrrolate (10.7%) or no anticholinergic (11.4%).[126] Similarly, surgical patients who were randomized to receive atropine had significantly less nausea than those given glycopyrrolate.[127] Atropine is a tertiary amine that can readily cross the blood-brain barrier and produce central effects, whereas glycopyrrolate is a quaternary amine that does not penetrate the blood-brain barrier. The beneficial effects of atropine on nausea and vomiting are likely secondary to a central nervous system effect.

Several randomized clinical trials have been performed to determine whether anticholinesterase administration results in an increase in the incidence of postoperative nausea and vomiting. Unfortunately, most study populations were small (39–120 patients). Two systematic reviews have been conducted to address this limitation. Tramer

TABLE 28.6 Early and Delayed Postoperative Nausea and Vomiting With Neostigmine Versus Control—Results of a Metaanalysis

Outcome	Anticholinergics	Number of Studies	Number of Participants	Relative Risk (95% CI)
Early nausea (0-6 h)	Atropine and Glycopyrrolate	6	584	1.24 (0.86-1.80)
	Atropine	1	79	0.67 (0.36-1.26)
	Glycopyrrolate	5	505	1.39 (0.97-1.99)
Early vomiting (0-6 h)	Atropine and Glycopyrrolate	8	768	1.05 (0.72-1.55)
	Atropine	2	199	0.75 (0.52-1.08)
	Glycopyrrolate	6	568	1.35 (0.88-2.06)
Delayed nausea (6-24 h)	Glycopyrrolate	4	337	1.09 (0.76-1.57)
Delayed vomiting (6-24 h)	Glycopyrrolate	4	337	1.01 (0.58-1.78)

and Fuchs-Buder analyzed eight trials with data on 1134 patients that compared reversal with neostigmine or edrophonium with spontaneous recovery from long- or intermediate-acting NMBDs.[128] An analysis of the neostigmine data across all trials and doses revealed no evidence of an increased risk of early and late nausea and vomiting when neostigmine was administered. However, some evidence in adults suggested that antagonism with larger doses of neostigmine (2.5 mg) might increase the incidence of these events. No evidence was found for this effect with edrophonium. A later systematic review evaluated the effect of neostigmine on postoperative nausea and vomiting while considering the different anticholinergics as confounding variables.[125] Ten randomized trials (933 patients) that compared neostigmine to inactive control were included. The combination of neostigmine with either glycopyrrolate or atropine did not increase the incidence of nausea or vomiting, nor was there an increased risk when large doses of neostigmine were compared with smaller doses (Table 28.6). Atropine was associated with a reduction in the risk of vomiting, but glycopyrrolate was not. In conclusion, there is at present insufficient evidence to conclude that neostigmine or edrophonium is associated with an increased risk of postoperative nausea and vomiting.

Cardiovascular Effects. Pronounced vagal effects are observed following the administration of anticholinesterases—bradycardia and other bradyarrhythmias, such as junctional rhythms, ventricular escape beats, complete heart block, and asystole, have been reported. The time course of these bradyarrhythmias parallels the onset of action of the anticholinesterases, with the most rapid onset observed with edrophonium, slower for neostigmine, and slowest for pyridostigmine.[90] In order to counteract these cardiovascular effects, atropine and glycopyrrolate are administered concurrently with anticholinesterases. Atropine and glycopyrrolate have muscarinic (parasympathetic) blocking effects, but do not block nicotinic receptors. Atropine has a more rapid onset of action (approximately 1 minute) compared with glycopyrrolate (2-3 minutes), although the duration of action of both agents is similar (30–60 minutes). Despite the concurrent administration of anticholinergic drugs, a high incidence of bradyarrhythmias is observed following anticholinesterase reversal (up to 50%–60% of patients in some studies).[129] The risk of arrhythmias is influenced by the type of anticholinesterase and anticholinergic used, the dose of anticholinesterase and anticholinergic administered, and background anesthetic used (opioid-based vs. volatile anesthetic and type of NMBD).

Several investigations have examined the heart rate and rhythm responses to various anticholinesterase/anticholinergic combinations. In general, it is preferable to use atropine with edrophonium because the onset of action of both drugs is rapid. Edrophonium-atropine mixtures induced small increases in heart rate, whereas edrophonium-glycopyrrolate mixtures caused decreases in heart rate and occasionally severe bradycardia.[130] Similarly, the onset of cholinergic effects of neostigmine coincides with the onset of the anticholinergic effects of glycopyrrolate; glycopyrrolate is superior to atropine in protecting against neostigmine-induced bradyarrhythmias.[131] When atropine is given with edrophonium (0.5-1.0 mg/kg), doses of 5 to 7 μg/kg are recommended, although larger doses may be used in certain circumstances.[130,132] If glycopyrrolate is given with neostigmine, minimal changes in heart rate are observed if a dose equivalent of one fourth the dose of neostigmine is used (e.g., 1 mg glycopyrrolate with 4 mg of neostigmine).[131] Because the onset of action is slow with pyridostigmine, tachycardia may be observed when either atropine or glycopyrrolate is coadministered.

More recent investigations have examined the impact of atropine and glycopyrrolate, given with neostigmine, on autonomic control in the postoperative period. During physiologically stressful events, control of heart rate and arterial blood pressure is regulated by the sympathetic and parasympathetic nervous systems. Anticholinergic drugs attenuate the efferent parasympathetic regulation of heart rate and suppress cardiac baroreflex sensitivity and heart rate variability. This suppression of the parasympathetic system may predispose patients to cardiac arrhythmias following surgery. Marked decreases in baroreflex sensitivity and high-frequency heart rate variability have been observed in healthy volunteers given either atropine (20 μg/kg) or glycopyrrolate (7 μg/kg).[133] Although the times required to return to baseline values were prolonged in both groups, recovery times were significantly longer in the subjects given atropine (177-212 minutes) compared with those administered glycopyrrolate (82-111 minutes). Similar effects have been observed in healthy patients undergoing general anesthesia reversed with neostigmine and anticholinergics.[134] Neuromuscular blockade was antagonized with neostigmine 50 µg/kg and either atropine 20 µg/kg or glycopyrrolate 8 µg/kg. Two hours after giving neostigmine, patients given atropine had persistent impairment of baroreflex sensitivity and high-frequency heart rate variability, whereas these variables had returned to baseline values in patients receiving glycopyrrolate. These investigations demonstrate that the parasympathetic nervous system control of heart rate is less impaired by glycopyrrolate than by atropine.

Bronchoconstriction. Bronchospasm can occur after the administration of neostigmine in surgical patients.[135,136] Anticholinesterases (e.g., neostigmine) stimulate muscarinic receptors in airway smooth muscle; stimulation of these receptors can provoke bronchoconstriction. Neostigmine and pyridostigmine induce a phosphatidylinositol response (a reflection of smooth muscle contraction induced by a muscarinic agonist) in airway muscle, which can result in bronchoconstriction.[137] This response was inhibited in the presence of atropine, a direct bronchodilator. Edrophonium did not induce a phosphatidylinositol response. In patients with cervical spinal cord injuries, neostigmine alone caused bronchoconstriction, whereas neostigmine combined with glycopyrrolate caused bronchodilation.[138] The risk of perioperative bronchospasm appears low if anticholinesterases are administered concurrently with anticholinergics.

SUGAMMADEX REVERSAL OF NEUROMUSCULAR BLOCKADE

Sugammadex (Org 25969) is a modified γ-cyclodextrin and the first selective relaxant–binding agent based on an encapsulating principle for inactivation of a neuromuscular blocking drug (*su* refers to sugar, and *gammadex* refers to the structural molecule γ-cyclodextrin). This principle for reversal of rocuronium- and vecuronium-induced neuromuscular blockade was first introduced into clinical practice in 2008 and is now available for pediatric and adult anesthesia in most countries worldwide, including the United States and China. The complex formation of sugammadex and rocuronium or vecuronium occurs at all levels of neuromuscular blockade (profound through shallow) and results in a more fast-acting pharmacologic reversal when compared with anticholinesterase drugs. Consequently, sugammadex may markedly reduce postoperative residual neuromuscular blockade in the PACU.[139]

Structure-Activity Relationships and Mechanism of Action

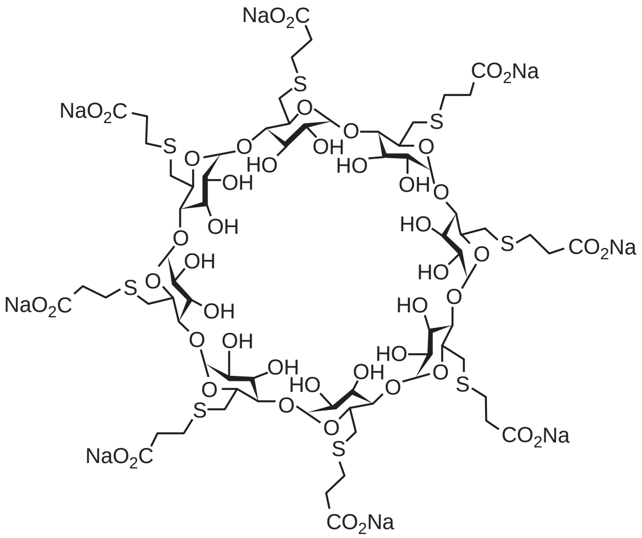

Fig. 28.15 Structure of the synthetic γ-cyclodextrin sugammadex (Org 25969). (From Bom A, Bradley M, Cameron K, et al. A novel concept of reversing neuromuscular block. Chemical encapsulating of rocuronium bromide by a cyclodextrin-based synthetic host. *Angew Chem.* 2002;41:266–270.)

The three natural unmodified cyclodextrins consist of six, seven, and eight cyclic oligosaccharides (i.e., dextrose units joined through one to four glycosyl bonds) and are called α-, β-, and γ-cyclodextrins, respectively.[140,141] Their three-dimensional structure resembles a hollow, truncated cone or a doughnut. The structure has a hydrophobic cavity and hydrophilic exterior because of the presence of polar hydroxyl groups. Hydrophobic interactions trap the lipophilic molecules in the cyclodextrin cavity, thereby resulting in the formation of a water-soluble guest-host complex. Sugammadex is built on this principle ring structure but is a modified γ-cyclodextrin. Although an unmodified γ-cyclodextrin possesses a larger lipophilic cavity (7.5-8.3 Å) than α- or β-cyclodextrins, it is still not deep enough to accommodate the larger rigid structure of the rocuronium molecule. Therefore the cavity is modified by adding eight side chains to extend it to 11 Å for better accommodation of the four hydrophobic steroidal rings of rocuronium. Furthermore, at the end of these side chains, negatively charged carboxyl groups are added to enhance electrostatic binding to the positively charged quaternary nitrogen of rocuronium (Fig. 28.15).[141,142] The stability of the rocuronium-sugammadex complex is a result of the combination of intermolecular forces (van der Waals forces), including thermodynamic (hydrogen bonds) and hydrophobic interactions.[141-143] Sugammadex forms a rigid complex in a 1:1 ratio with steroidal NMBDs (rocuronium and vecuronium) (Fig. 28.16).[141] There is some binding affinity with pancuronium, but this interaction is too low to have a significant clinical effect. The molecular mass of the sugammadex-rocuronium complex is 2532 g/mol (sugammadex 2002 g/mol and rocuronium 530 g/mol), and that of the sugammadex-vecuronium complex is 2640 g/mol (vecuronium 638 g/mol).[141] The rocuronium-sugammadex complex exists in an equilibrium with an association/dissociation rate of 1 molar concentration of sugammadex and rocuronium of 25,000,000:1, which means that sugammadex forms a very rigid complex and encapsulates rocuronium at 25 million times the rate that one molecule complex dissociates. The affinity of sugammadex toward vecuronium is 2.5 times smaller, but still high enough to form a tight complex.[141] Rapid binding of rocuronium and sugammadex results in removal of free rocuronium molecules from the plasma. This creates a

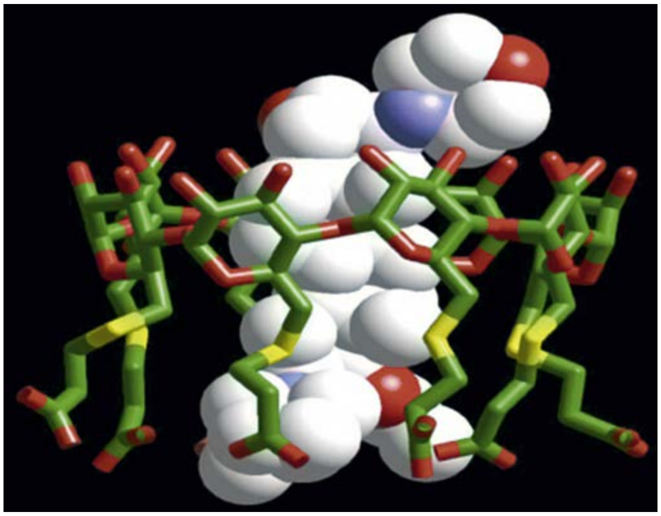

Fig. 28.16 **The sugammadex-rocuronium complex.** (From Bom A, Bradley M, Cameron K, et al. A novel concept of reversing neuromuscular block. Chemical encapsulating of rocuronium bromide by a cyclodextrin-based synthetic host. *Angew Chem.* 2002;41:266–270.)

concentration gradient favoring movement of the remaining rocuronium molecules from the effect site at the neuromuscular junction into plasma, where the drug is encapsulated by free sugammadex molecules. Neuromuscular blockade is quickly reversed as rocuronium is removed from the binding sites at the neuromuscular junction. Sugammadex administration results in an increase in the total plasma concentration of rocuronium (free and that bound to sugammadex).[144] Because sugammadex acts as a selective binding agent and has no direct or indirect action on the molecular components of cholinergic transmission (cholinesterase, nicotinic receptors, or muscarinic receptors), the need for coadministration of anticholinergic drugs is eliminated.[145]

Pharmacokinetics

The pharmacokinetic profile of sugammadex and rocuronium has been investigated in healthy volunteers and surgical patients.[146] Sugammadex, in a dose range of 0.1 to 8.0 mg/kg in healthy adult volunteers (without neuromuscular blockade), exhibited a dose-linear pharmacokinetic profile, a volume distribution of 18 L, an elimination half-life of 100 minutes, and a plasma clearance rate of 120 mL/min, with up to 80% of the dose being excreted in urine over 24 hours.[146] After encapsulation by sugammadex, rocuronium is less free to distribute to compartments other than those associated with the compartment in which sugammadex resides. During an infusion of rocuronium to maintain a stable depth of neuromuscular blockade, administration of sugammadex increased the measured plasma concentration of rocuronium; rocuronium redistributed from the effect compartment (including the neuromuscular junction) to the central compartment (mostly as the sugammadex complex) as it was encapsulated by sugammadex.[144] The volume of distribution of rocuronium decreases with increasing doses of sugammadex until the volume of distribution of rocuronium approaches the volume of distribution of sugammadex at higher doses.[144] Encapsulation changes the pharmacokinetics of rocuronium. In the absence of sugammadex, rocuronium is eliminated mainly by biliary excretion (>75%) and to a lesser degree by renal excretion (10%-25%).[147] The main difference in the pharmacokinetic profile of sugammadex and rocuronium is that the clearance of sugammadex is approximately three times slower than that of rocuronium.[146] The rate and amount of urinary excretion of rocuronium when administered alone is slow and small, but when sugammadex (a dose of 2.0 mg/kg or more) is administered, the plasma clearance of rocuronium is decreased by a factor of more than two.[146] This decreased clearance occurs because the biliary route of excretion becomes unavailable for the rocuronium-sugammadex complex as the large size of this complex prohibits additional renal excretion. The clearance of rocuronium after binding by sugammadex decreases to a value approaching the glomerular filtration rate (120 mL/min).[147] However, the renal excretion of rocuronium is increased by more than 100% after administration of 4.0 to 8.0 mg/kg of sugammadex.[147] Following the administration of sugammadex, encapsulation of rocuronium in the plasma results in a rapid decrease in free rocuronium in this compartment, although the total plasma concentration of rocuronium (both free and bound by sugammadex) increases. This results in a concentration gradient between the relatively high level of free rocuronium in the effect compartment (the neuromuscular junction) and the low level in the plasma compartment.[144] As a result, free rocuronium molecules rapidly diffuse towards the plasma compartment and are encapsulated by sugammadex. Thus the increase in plasma levels of rocuronium after sugammadex administration illustrates the mechanism responsible for the rapid reversal of neuromuscular blockade by sugammadex.

Because renal excretion is the primary route for the elimination of sugammadex and the rocuronium-sugammadex complex, studies on elimination by dialysis have considerable relevance in clinical practice. In a small subset of patients with severe renal impairment, an investigation on dialysis showed that the clearance of sugammadex and rocuronium in blood was 78 and 89 mL/min, respectively. Therefore hemodialysis using a high-flux dialysis method is effective in removing sugammadex and the sugammadex-rocuronium complex in patients with severe renal impairment.[148]

Pharmacodynamics

Clinical Use of Sugammadex in Healthy Patients

The first human exposure of sugammadex in male volunteers showed a large dose-dependent, more rapid recovery time from a rocuronium-induced neuromuscular blockade with sugammadex (0.1-8.0 mg/kg) as compared with placebo.[146] Administration of 8 mg/kg of sugammadex 3 minutes after a bolus dose of 0.6 mg/kg of rocuronium resulted in a recovery of the TOF ratio to 0.90 within 2 minutes compared with 52 minutes for placebo. Decreasing the dose of sugammadex to 4 mg/kg resulted in recovery of the TOF ratio to 0.90 in less than 4 minutes.[146] Similar recovery times were found in a study in which surgical patients received 0.6 mg/kg rocuronium, followed by different doses of sugammadex or placebo administered at a TOF count of 2.[149] Sugammadex reduced the median recovery time in a dose-dependent manner from 21 minutes in the placebo group to 1.1 minutes in the group receiving 4.0 mg/kg of sugammadex.[149] In another study, administration of sugammadex resulted in a more rapid and effective recovery from a rocuronium (0.6 mg/kg) or vecuronium

(0.1 mg/kg) neuromuscular blockade.[150] After a dose of 4.0 mg/kg of sugammadex, the mean recovery time to a TOF ratio of 0.90 was 1.1 minutes and 1.5 minutes after rocuronium and vecuronium, respectively (Figs. 28.17 and 28.18).[150] Reversal of neuromuscular blockade with larger doses of rocuronium (1.0–1.2 mg/kg) by different doses of sugammadex (2.0–16.0 mg/kg) at different time points (3–15 minutes after rocuronium) showed a dose-dependent, rapid, and effective reversal compared with placebo.[151-154]

Whereas anticholinesterase drugs, such as neostigmine, are unable to reverse deeper levels of neuromuscular blockade (e.g., posttetanic count of 1-2) because of a ceiling effect, sugammadex is effective in reversing profound neuromuscular blockade.[152,155] Optimal doses of sugammadex of 4.0 mg/kg produced prompt recovery of the TOF ratio to 0.90 within minutes (Table 28.7).[150-155] Therefore reversal of moderate and profound rocuronium and vecuronium neuromuscular blockades can be reliably achieved by administration of sugammadex, provided a dose of 2.0 and 4.0 mg/kg, respectively, is used. Because neostigmine has neuromuscular effects when given alone, some spontaneous recovery of the TOF should be evident before it is given. In contrast, sugammadex has no neuromuscular effects when given alone. Accordingly, sugammadex can be given even if there is no response to TOF stimulation. Sugammadex allows a profound neuromuscular blockade to continue until the end of surgery.

In contrast to the anticholinesterase drugs (e.g., neostigmine), intense neuromuscular blockade (no response to TOF and PTC stimulation) can be reversed by sugammadex immediately after the administration of rocuronium. In a multicenter investigation, patients were randomized to receive 1.2 mg/kg of rocuronium followed 3 minutes later by 16 mg/kg of sugammadex or a dose of 1.0 mg/kg of succinylcholine.[156] The mean time to 90% recovery of the first twitch (T1) from the start of sugammadex administration was 2.9 minutes and to a recovery of the TOF ratio to 0.90 was 2.2 minutes.[156] In contrast, the spontaneous recovery time from a succinylcholine neuromuscular blockade to 90% recovery of T1 was 10.9 minutes. Thus reversal of large doses of rocuronium with 16 mg/kg sugammadex was significantly faster than spontaneous recovery from succinylcholine (Fig. 28.19).[156] These findings were confirmed in a randomized trial that assessed how rapidly spontaneous ventilation could be reestablished after rapid sequence induction of anesthesia and intubation of the trachea, using either the combination of rocuronium (1.0 mg/kg)–sugammadex (16 mg/kg) or succinylcholine (1.0 mg/kg).[157] The median time from tracheal intubation to spontaneous ventilation was 406 seconds with succinylcholine and 216 seconds with rocuronium-sugammadex (Table 28.8).[157] These data demonstrated that sugammadex reversal of a large-dose rocuronium neuromuscular

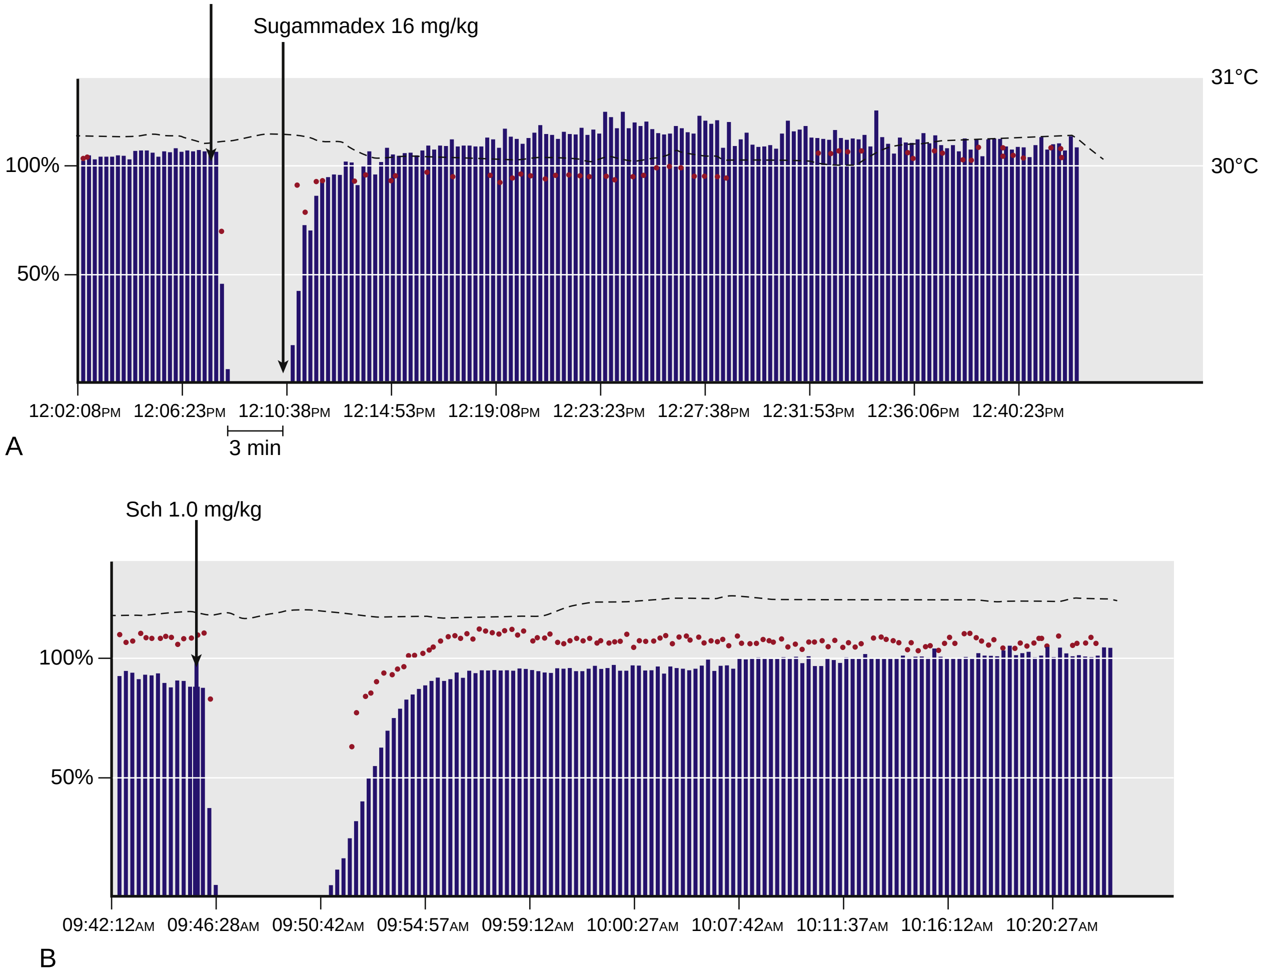

Fig. 28.19 (A) Recovery of T1 twitch height *(blue tracings)* and the train-of-four (TOF) ratio *(red dots)* after the administration of 1.2 mg/kg of rocuronium, followed 3 minutes later by 16 mg/kg of sugammadex, both given intravenously. Recovery to a first twitch height (T1) of 90% and a TOF ratio of 0.94 occurred 110 seconds later. The onset-offset time with this sequence (i.e., time from the end of the injection of rocuronium until T1 recovery to 90%) was 4 minutes, 47 seconds. (B) Effects of administering 1.0 mg/kg of succinylcholine *(Sch)* with spontaneous recovery to a T1 recovery to 90% occurring after 9 minutes, 23 seconds. *Black dashed line* represents hand skin temperature (°Celsius). (From Naguib M. Sugammadex: another milestone in clinical neuromuscular pharmacology. *Anesth Analg.* 2007;104:575–581.)

blockade was not only significantly faster than spontaneous recovery from succinylcholine, but that spontaneous ventilation could be restored more rapidly (i.e., this dose can be used to replace succinylcholine for endotracheal intubation). In clinical practice and during an unexpected difficult airway (cannot intubate, cannot ventilate scenario), a rocuronium neuromuscular blockade may be reversed by sugammadex immediately in order to restore spontaneous ventilation.

When sugammadex was compared with neostigmine or edrophonium, the time course of neuromuscular recovery was markedly different.[158-160] In a clinical study, patients received 0.6 mg/kg of rocuronium after which neuromuscular blockade was sustained with supplemental boluses of rocuronium given at the reappearance of the second twitch (second response to TOF stimulation or T2).[158] Fifteen minutes after the last dose of rocuronium either 70 µg/kg of neostigmine, 1 mg/kg of edrophonium, or 4.0 mg/kg sugammadex was administered. The average time to achieve a TOF ratio of 0.90 was 10 times longer after the administration of neostigmine than it was after sugammadex (1044 seconds vs. 107 seconds) and 3 times longer after the administration of edrophonium (331 seconds). In another study by Blobner and associates, similar differences were found when comparing reversal of rocuronium at the reappearance of the second twitch in the TOF response using 2 mg/kg sugammadex versus neostigmine 50 µg/kg.[159] This was also confirmed in an investigation that assessed the efficacy of sugammadex versus neostigmine for reversal of profound rocuronium-induced neuromuscular blockade.[160] More than 97% of patients reversed with sugammadex (4.0 mg/kg) at a PTC of 1 to 2 recovered to a TOF ratio of 0.90 within 5 minutes. In contrast, 73% of the patients administered neostigmine (70 µg/kg) recovered between 30 and 60 minutes after administration, with 23% requiring more than 60 minutes to recover to a TOF ratio of 0.90 (Fig. 28.20).

A randomized trial compared the efficacy of sugammadex reversal of a rocuronium (0.6 mg/kg) neuromuscular blockade with that of neostigmine reversal of a cisatracurium (0.15 mg/kg) neuromuscular blockade.[161] Time from the start of administration of reversal agent sugammadex 2.0 mg/kg or neostigmine 50 µg/kg) to recovery of the TOF

ratio to 0.90 was 4.7 times faster with sugammadex than with neostigmine, 1.9 versus 9.0 minutes, respectively.

Unlike with neostigmine or edrophonium, the choice of anesthetic (e.g., propofol vs. sevoflurane) does not influence the ability of sugammadex to reverse rocuronium-induced neuromuscular blockade.[162,163] Provided that sugammadex is used in recommended dosages according to the level of neuromuscular blockade, a small risk exists of incomplete neuromuscular recovery or reoccurrence of neuromuscular blockade following surgery.

Clinical Use of Sugammadex in Pediatric and Older Adult Patients

PEDIATRICS. The use of sugammadex in pediatric patients was examined in a study enrolling 8 infants (28 days to 23 months), 24 children (2-11 years), and 31 adolescents (12-17 years).[164] Patients were anesthetized with propofol and opioids and received rocuronium 0.6 mg/kg. At the reappearance of T2 (second twitch), patients were given sugammadex 0.5, 1.0, 2.0, or 4.0 mg/kg or placebo. Recovery time to a TOF ratio of 0.90 decreased in a dose-dependent manner in all age groups. Residual neuromuscular blockade or recurarization was not observed, and no side effects were reported. In a more recent case report, sugammadex was used successfully in reversing a vecuronium-induced neuromuscular blockade in a 7-month-old infant.[165] Another case report described a 2-year-old patient who received readministration of rocuronium for reoperation after an initial successful reversal with sugammadex.[166] A recent systematic review showed that compared with neostigmine or placebo, sugammadex can reverse a rocuronium-induced neuromuscular blockade more rapidly with lower incidence of bradycardia.[167]

While sugammadex can be used safely in children and adolescents (2-17 years old), information on the use of sugammadex in pediatric patients less than 2 years old is still limited.

OLDER ADULT PATIENTS. Reversal of neuromuscular blockade by sugammadex has been assessed in older patients. One hundred and fifty patients were divided into three groups; an adult group (18–64 years old), an older adult group (65–75 years old), and an oldest adult group (75 years or older).[168] Patients received an intubating dose of rocuronium 0.6 mg/kg with maintenance doses of 0.15 mg/kg as required. Sugammadex 2.0 mg/kg was administered after the last dose of rocuronium at the

reappearance of T2. Recovery of neuromuscular blockade by sugammadex was slightly (0.7 minutes) faster in patients younger than 65 years of age. In general, a prolonged circulation time secondary to a reduced cardiac output in older patients was anticipated to result in a longer recovery time from neuromuscular blockade after administration of sugammadex.[169,170] However, based on these results, no dose adjustments are needed in older patients.[168] Yet, if it is necessary to achieve a fast recovery in a short period of time, a higher dose of sugammadex might be considered.[171]

Clinical Use of Sugammadex in Special Patient Populations

Cardiac Disease. Studies evaluating the safety and efficacy of sugammadex in patients with underlying cardiovascular disease have not demonstrated an effect of sugammadex on electrocardiogram (no indication of a possible prolongation effect on the QTc interval).[172,173] A study designed to evaluate the effects of sugammadex on QTc prolongation in healthy subjects (in doses up to 32 mg/kg, alone or in combination with rocuronium or vecuronium) revealed that the administration of sugammadex was not associated with QTc prolongation.[173] In a case report of a patient with long QT syndrome, a vecuronium neuromuscular blockade was reversed with sugammadex 2 mg/kg without adversely affecting the QT interval.[174] Based on current data, sugammadex reversal is not associated with cardiovascular side effects in healthy patients or in those with cardiovascular comorbidities (also see earlier section Complications Associated With Inhibitors of Acetylcholinesterase).

Pulmonary Disease. Patients with a history of pulmonary disease have an increased risk of postoperative pulmonary complications such as pneumonia, respiratory failure, and exacerbation of the underlying pulmonary disease.[175] Sugammadex has been studied in patients with pulmonary disease.[175] Seventy-seven surgical patients with a diagnosis or known history of pulmonary disorders received sugammadex in doses up to 4 mg/kg in order to reverse a rocuronium neuromuscular blockade. As in other adult patient groups, reversal of a rocuronium-induced neuromuscular blockade was rapid, and there were no signs of residual neuromuscular blockade or recurarization.[176] Of the 77 patients treated with sugammadex, 2 patients developed bronchospasm, 1 minute and 55 minutes respectively, after the administration of sugammadex. Both patients were asthmatic, and there was no evidence that these symptoms were related to sugammadex. In other subsets of high-risk pulmonary patients (cystic fibrosis and end-stage lung disease), the successful use of sugammadex has been reported.[177] Reversal of a neuromuscular blockade with sugammadex has potential advantages compared with anticholinesterase drugs (e.g., neostigmine) in patients with pulmonary disease because sugammadex lacks interactions with the muscarinic cholinergic system, and there is no need for coadministration of anticholinergic compounds (also see section, Complications Associated With Inhibitors of Acetylcholinesterase).

Renal Failure. The use of sugammadex to reverse rocuronium neuromuscular blockade was investigated in 15 patients with severe renal impairment (creatinine clearance <30 mL/min) and compared with 15 patients with normal renal function (creatinine clearance >80 mL/min).[178] Sugammadex 2 mg/kg was administered at the reappearance of T2. There were no differences between groups in the recovery profile or the incidence of residual blockade after sugammadex (Table 28.9). In another study, the reversal of a rocuronium-induced deep neuromuscular blockade with sugammadex 4.0 mg/kg in patients with severe renal impairment (creatinine clearance <30 mL/min) showed a fast and stable reversal.[179] Sugammadex and sugammadex-rocuronium complex exposure is increased in patients with moderate and severe renal failure due to the decreased renal clearance.[180] The use of sugammadex in renal transplantation was described in two cases in which sugammadex was used for reversal of a rocuronium-induced neuromuscular block in pediatric patients and showed a fast and complete reversal without signs of residual neuromuscular blockade or recurarization.[181] More recently, the long-term efficacy and safety of rocuronium and sugammadex in patients undergoing renal transplantation were described in 57 patients diagnosed with severe renal failure.[182] Rocuronium and sugammadex appeared to be efficacious and safe in patients undergoing renal transplantation. Because complete elimination of the sugammadex-rocuronium complex remains poorly understood in renal impairment, sugammadex is at present not recommended for use in patients with severe renal failure. However, it can be used in patients with mild or moderate renal dysfunction as its safety profile is similar to that of healthy patients.[178] Theoretically, because of the molecular mass of the rocuronium/vecuronium-sugammadex complex, it is possible to decrease the plasma levels of this complex by dialysis. Hemodialysis using a high-flux dialysis method has been demonstrated to be effective in removing sugammadex and the sugammadex-rocuronium complex in patients with severe renal impairment.[148]

HEPATOBILIARY DISEASE. Sugammadex has not been studied in animal models or in patients with hepatic impairment. However, it is known that the biliary route of excretion becomes unavailable for either sugammadex or the rocuronium/vecuronium-sugammadex complex because the large size of this complex prohibits such excretion.[183] A population pharmacokinetic/pharmacodynamic (PK-PD) model was used to simulate the scenario of an immediate reversal, and reversal of a profound rocuronium-induced neuromuscular blockade in patients with hepatic impairment.[183] Under such study conditions, hepatic impairment had little effect on the reversal time when sugammadex (16 mg/kg) was administered 3 minutes after rocuronium (1.2 mg/kg). However, in other scenarios (sugammadex 2 mg/kg at reappearance of T2 and 4 mg/kg after 15 minutes), recovery from a rocuronium-induced (1.2 mg/kg) neuromuscular blockade was predicted to be longer than that seen in healthy patients.[183] In patients with hepatobiliary disease, the recovery of neuromuscular function after sugammadex administration will likely be faster than reversal with anticholinesterase drugs (but not be as rapid as patients without hepatobiliary disease). The explanation of the slower reversal is not yet fully understood and needs to be investigated in clinical studies. Based on limited available data, sugammadex should be used with caution in patients with hepatobiliary disease.

OBESITY. Patients with obesity, particularly morbid obesity (body mass index [BMI] > 40 kg/m^2), are at risk for cardiovascular and respiratory complications perioperatively.[184] These patients are susceptible to critical respiratory events in the postoperative period, including hypoventilation, hypoxia, airway obstruction, and acute respiratory failure.[38,68] The presence of postoperative residual neuromuscular blockade may further increase the risk for postoperative complications in these patients by producing impairment of the integrity of the upper airway and upper airway collapse.[33,34] Therefore a rapid and complete reversal of neuromuscular blockade must be achieved before tracheal extubation is attempted. In this setting, sugammadex may have a more favorable recovery profile than traditional anticholinesterase drugs because it provides a more reliable recovery of neuromuscular functions and a less frequent risk of incomplete neuromuscular recovery.[184] A key issue is determining the appropriate dose of sugammadex to administer in a morbidly obese patient that is sufficient to capture remaining NMBD molecules. Whereas the dosing of NMBDs in obese patients should be based on lean/ideal body weight (because these drugs are hydrophilic and their volume of distribution is minimally affected by obesity), the dosing of sugammadex in obese patients is currently under debate. In order to ensure complete neuromuscular recovery, the dose of sugammadex must be sufficient to affect the gradient between the peripheral and central compartments and effectively encapsulate all rocuronium molecules. An inadequate dose of sugammadex may be incapable of sustaining this redistribution of rocuronium and lead to reoccurrence of the neuromuscular blockade.

The current product monograph recommends calculating the sugammadex dose based on the patient's actual body weight. However, because the low volume of distribution at steady state (estimated at 0.16 L/kg) restricts distribution to the intravascular space, it might be relevant to determine the dose of sugammadex based on the lean/ideal body weight and not on the actual body weight.[178] However, in a recently published pooled analysis (27 trials) on the use of sugammadex in patients with obesity (BMI > 30 kg/m^2), the authors concluded that the recommended dose on actual body weight provided rapid recovery from neuromuscular blockade in both obese and nonobese patients and that no dose adjustments should be undertaken in the obese patient.[185] Several studies have investigated the dosage of sugammadex based on lean or variations on the lean/ideal body weight.[186-189] In one investigation, a sugammadex dose of 4 mg/kg based on a lean/ideal body weight calculation was administered to morbidly obese patients during a profound rocuronium neuromuscular blockade.[188] Approximately 40% of these patients were inadequately reversed with a lean/ideal body weight–based dose of sugammadex. In these patients, an additional dose of sugammadex 2 mg/kg based on lean/ideal body weight was required to achieve a TOF ratio 0.90. The conclusion of the authors was that a sugammadex dose calculated according to lean/ideal body weight was insufficient for reversing both profound and moderate blockade in a considerable number of morbidly obese patients.[188]

In another study in morbidly obese patients, investigators examined reversal of a moderate level of a rocuronium neuromuscular blockade (at T1-T2) using a dose of sugammadex of 2.0 mg/kg.[187] Four different weight corrections were used: lean/ideal body weight, lean/ideal body weight +20%, lean/ideal body weight +40%, and actual body weight. This study demonstrated that a moderate rocuronium neuromuscular blockade could be effectively reversed with sugammadex 2.0 mg/kg using the calculation lean/ideal body weight + 40%.[187] In a more recent study, these findings were confirmed.[190] However, longer and larger interindividual variability of recovery times occur when dosing is based on lean/ideal body weight compared with dosing based on actual body weight.[187,188] Additionally, reoccurrence of neuromuscular blockade after suboptimal dosing of sugammadex has been reported in a morbidly obese patient.[189] Hence until more data are available, the dose of sugammadex should be based on the actual body weight.

CESAREAN SECTION AND PREGNANT PATIENTS. Induction of general anesthesia in late pregnancy and for patients undergoing cesarean section typically involves a rapid sequence induction of anesthesia with either thiopental or propofol and a rapid-onset NMBD. For decades, succinylcholine has been the prototypic NMBD used in these procedures to produce optimal endotracheal intubation conditions.[191] Rocuronium is an acceptable alternative to succinylcholine in rapid sequence induction of anesthesia procedures; rocuronium in doses larger than 1.0 mg/kg not only provides onset of action within 60 seconds, but also provides identical intubation conditions compared with succinylcholine.[192] However, the duration of action of rocuronium in dosages of 1.0 mg/kg or greater will result in a profound neuromuscular blockade of long duration (often more than 2 hours). Furthermore, the risk of failed intubation in the obstetric population is at least eight times higher compared with nonpregnant females.[193] In case of a failed endotracheal intubation scenario or a "cannot intubate, cannot ventilate" situation, rocuronium, even in dosages up to 1.2 mg/kg, can be immediately reversed with sugammadex 16 mg/kg.[156]

Preclinical animal data demonstrated that uteroplacental transfer of sugammadex is very small (<2% to 6%). Sugammadex does not have negative effects on pregnancy or on embryonic, fetal, or postnatal development.[191,194,195] Although no data are available about the excretion of sugammadex in human breast milk, excretion in breast milk is likely minimal, with insignificant clinical impact because oral absorption of cyclodextrins in general is small. Therefore sugammadex can be used in breastfeeding females. In two case series examining obstetric patients who received rocuronium and sugammadex (7 and 18 patients), no side effects were observed.[194,195] The efficacy and safety of sugammadex in obstetric anesthesia have not been determined; yet serious adverse events for the mother or the neonate have not been reported after sugammadex.

Neuromuscular Disorders. Neuromuscular disorders are frequently associated with an increased incidence of perioperative respiratory complications due to muscle weakness.[196,197] In these patient groups, administration of succinylcholine is often contraindicated and associated with potentially life-threatening side effects. The use of nondepolarizing NMBDs can on occasion be associated with prolonged spontaneous neuromuscular recovery, even after a single dose. Consequently, these patients have an increased risk for postoperative muscle weakness of multifactorial origin, one being residual neuromuscular blockade.[196,197] Prompt recovery of neuromuscular function is essential to optimize patient safety and reduce the risk of pulmonary complications. However, reversal with anticholinesterase (e.g., neostigmine), especially in neuromuscular disorders, can be associated with postoperative complications.[197]

Multiple case reports and case series describe the use of sugammadex in patients with various neuromuscular disorders such as myasthenia gravis, myotonic dystrophy, and spinal muscular atrophy (Fig. 28.21).[197-204] In general, dosing regimens for sugammadex were consistent with recommended doses adjusted to actual body weight and based on the level of neuromuscular blockade at the time of reversal. Sugammadex administration resulted in prompt reversal of neuromuscular blockade with a similar recovery profile as observed in normal patients. Although no studies have been performed in patients with neuromuscular disorders, the reported cases indicate that sugammadex should be considered as an alternative reversal drug (e.g., instead of neostigmine) in this patient population. These observations need to be confirmed in a larger series of patient studies.

Side Effects and Drug Interactions

Sugammadex is contraindicated in patients with known hypersensitivity to the drug. The potential for hypersensitivity is reported in several case reports. Hypersensitivity is a concern; however, this is difficult to study because hypersensitivity reactions occur rarely. In a recent retrospective analysis, the incidence of potential sugammadex-induced anaphylaxis at a single center over a period of 3 years was investigated. The overall incidence of intraoperative hypersensitivity was 0.22% (95% CI, 0.17%–0.29%), and the incidence of anaphylaxis was 0.059% (95% CI, 0.032%–0.10%). In total 15,479 patients were exposed to sugammadex in the study period and the incidence of anaphylaxis associated with sugammadex administration was 0.039% ($n = 6$; 95% CI, 0.014%–0.084%).[205] Prospective studies are needed to confirm the sugammadex anaphylaxis. Elevation of serum tryptase (positive predictive value of 93%, negative predictive value of 54%), skin testing (gold standard), and histamine levels in serum and urine are useful to confirm the diagnosis. Recently, a promising test, the basophil activation test, has been established to detect the causative compound of anaphylaxis with high specificity and sensitivity. However, more studies are needed to confirm this method to identify sugammadex-induced anaphylaxis.[206]

Other reported side effects include coughing, movement, parosmia (abnormal sense of smell), and elevated levels of *N*-acetyl-glucosaminidase in the urine.[183] Coughing and movement after the administration of sugammadex may have been due to the unmasking of inadequate anesthesia rather than a direct side effect of sugammadex. Initial studies showed a prolongation of activated partial thromboplastin and prothrombin time in healthy volunteers after sugammadex administration. However, in a more in-depth patient study that investigated the effect of sugammadex on postsurgical bleeding and coagulation variables, it was shown that sugammadex produced a limited, transient (<1 hour) increase in activated partial thromboplastin and

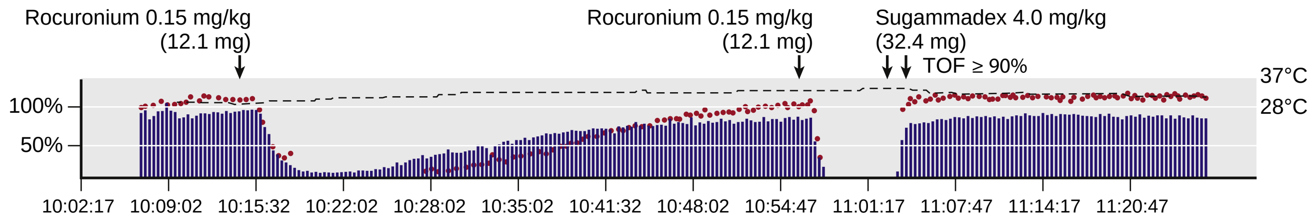

Fig. 28.21 Original tracing of sugammadex reversal in a patient with myasthenia gravis. The time to spontaneous recovery from the first profound rocuronium-induced neuromuscular blockade to a train-of-four *(TOF)* ratio was 36.5 minutes. The time from the start of the administration of sugammadex 4.0 mg/kg after the second dose of rocuronium to the recovery of the TOF ratio to 0.90 was 2.7 minutes. *Blue tracings* represent T1 recovery while *red dots* represent TOF ratio recovery. *Black dashed line* indicates hand skin temperature (degrees Celsius). (From de Boer HD, van Egmond J, Driessen JJ, et al. A new approach to anesthesia management in myasthenia gravis: reversal of neuromuscular blockade by sugammadex. *Rev Esp Anesthesiol Reanim*. 2010;57:81–84.)

prothrombin time but was not associated with increased risk of bleeding versus usual care.[207]

Cyclodextrins are a class of agents well known for their ability to form inclusion complexes with other compounds. Sugammadex forms a very tight complex with rocuronium or vecuronium in a 1:1 molecular ratio; however, because of its mechanism of action, it is possible that other relevant drug interactions may occur.[208] Theoretically, two important drug interactions can take place. First, sugammadex is capable of encapsulating endogenous or pharmaceutical molecules other than steroidal NMBDs, resulting in reduced efficacy of the encapsulated molecules. However, the ability to form complexes with steroidal or nonsteroidal molecules such as cortisone, atropine, and verapamil is clinically insignificant because the affinity for sugammadex is 120 to 700 times less than that of rocuronium.[208] In preclinical studies, an interaction of sugammadex with other steroidal compounds could be excluded up to a dose of sugammadex of 500 mg/kg/day.[209] Second, if the affinity of sugammadex for another molecule is very high, this molecule may displace rocuronium or vecuronium from the complex with sugammadex, resulting in reoccurrence of neuromuscular blockade. Both drug interactions may have potential clinical safety implications.[208] A modeling approach has been developed to evaluate 300 compounds (including the most commonly used drugs in the perioperative period) for possible displacement interactions with sugammadex.[208] In this screening, three compounds were identified as having possible displacement interactions: toremifene, fusidic acid, and flucloxacillin.[208] However, no clinically relevant reoccurrence of neuromuscular blockade was identified when sugammadex was used in combination with these drugs.[208] A clinical study reported that flucloxacillin did not cause reoccurrence of neuromuscular blockade after reversal with sugammadex; no clinically important displacement interaction was observed.[210]

Special Considerations

Reintubation of the Trachea After Initial Reversal of Neuromuscular Blockade With Sugammadex. Patients receiving sugammadex before extubation of the trachea who need reintubation require special consideration because the remaining circulating sugammadex molecules may potentially interfere with readministration of rocuronium or vecuronium. In this setting, two alternate strategies can reestablish a neuromuscular blockade. Within 24 hours of sugammadex administration, it is currently recommended that a nonsteroidal NMBD be used instead of rocuronium or vecuronium. This conservative approach is based on the maximum clearance time for sugammadex. However, preclinical and clinical studies have shown that it is possible to safely reestablish neuromuscular blockade with rocuronium earlier than 24 hours.[211] A modeling-based study in healthy volunteers revealed that high-dose rocuronium given 5 to 60 minutes after sugammadex reversal produced a complete neuromuscular blockade (T1 = 0%).[212] Rocuronium (1.2 mg/kg) administrated 5 minutes after sugammadex reversal produced a rapid onset of neuromuscular blockade (T1 = 0%), with a mean onset time of approximately 3 minutes. Thirty minutes after administration of sugammadex, an onset time of 1.5 minutes can be achieved with rocuronium (1.2 mg/kg). Hence an inverse relationship exists between the onset time and the time interval between sugammadex and the repeat dose of rocuronium, and a direct relationship exists between the duration of neuromuscular blockade and the time interval between sugammadex and the repeat dose of rocuronium.

Based on dose calculations using a model in which the equilibrium is described in the common volume of distribution of rocuronium and sugammadex, even a second reversal is possible using sugammadex with large doses between 8 and 20 mg/kg.[211]

Incomplete Reversal of Neuromuscular Blockade. Although sugammadex encapsulates rocuronium and vecuronium to form a rigid complex, case reports have described incomplete reversal of neuromuscular blockade.[151,213] In a dose-finding study, a case was described in which a temporary decrease in the TOF response was observed in a healthy patient after reversal with 0.5 mg/kg sugammadex.[213] The TOF ratio initially reached 0.70 before decreasing to 0.30 and then gradually increasing to 0.90 (Fig. 28.22). The authors hypothesized that the decrease in TOF ratio occurred because of redistribution of unbound rocuronium from the peripheral compartments, with insufficient sugammadex available for additional encapsulation of rocuronium. Similarly, incomplete reversal was reported in two healthy patients given suboptimal doses of sugammadex (0.5 mg/kg) during profound rocuronium-induced neuromuscular blockade.[151] In a study by Duvaldestin and associates, reversal of deep neuromuscular blockade with a low dose of sugammadex (0.5 and 1.0 mg/kg) found that five patients experienced recurrence of neuromuscular blockade.[163] In another study, both speed of reversal and effectiveness of sugammadex are dose-dependent; a single dose of 1.0 mg/kg of sugammadex (n = 15) administered at a deep neuromuscular blockade (PTC = 1) required

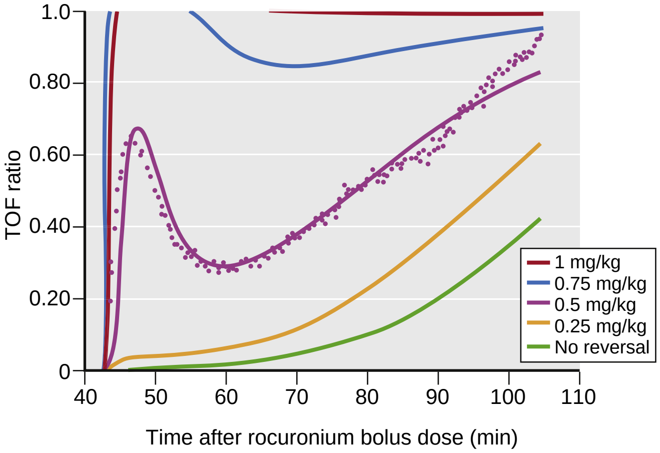

Fig. 28.22 The train-of-four data *(dots)* and the results of simulations *(solid lines)* of various sugammadex dosing amounts. Muscle relaxation rebound only occurs for sugammadex doses in a limited range. The simulations indicate that for this patient, doses larger than about 1 mg/kg are sufficient to achieve rapid muscle relaxation reversal and avoid muscle relaxation rebound. *TOF,* train-of-four. (From Eleveld DJ, Kuizenga K, Proost JH, et al. A temporary decrease in twitch response during reversal of rocuronium-induced muscle relaxation with a small dose of sugammadex. *Anesth Analg*. 2007;104:582–584.)

significantly longer time for reversal than a dose of 4.0 mg/kg ($n = 60$).[214] Interestingly, seven patients also exhibited residual ($n = 3$) and recurrence ($n = 4$) of neuromuscular blockade in the group of patients that received 1.0 mg/kg sugammadex. No patients who received the recommended dose of 4.0 mg/kg sugammadex had residual of recurarization of neuromuscular blockade. A similar pattern was observed with vecuronium-induced neuromuscular blockade. A longer reversal time and a higher incidence of residual and/or recurrence of neuromuscular blockade were noted in patients who received smaller (0.5 and 1.0 mg/kg) doses of sugammadex.[215] Therefore it is recommended that the dose be adjusted to the depth of neuromuscular blockade as underdosing of sugammadex is associated with an increased risk of residual neuromuscular blockade or recurrence of neuromuscular blockade.

Female Patients. Sugammadex may interact with hormonal contraceptive drugs. Possible capturing interactions, whereby unwanted encapsulation of a third drug by sugammadex reduces its clinical efficacy, have been investigated. In pharmacokinetic-pharmacodynamic simulations, it was predicted that 34% of (free) etonogestrel might be captured by 4 mg/kg sugammadex under very conservative modeling assumption conditions.[209] The interaction with this bolus dose of sugammadex resulted in a decrease in etonogestrel exposure, which was similar to the decrease seen after one missed daily dose of an oral contraceptive. Patients using hormonal contraceptives should be informed about the possible reduced effectiveness of hormonal contraceptive drugs after the administration of sugammadex. The use of an additional nonhormonal contraceptive method for the next 7 days should be considered in this patient population.

Electroconvulsive Therapy. Electroconvulsive therapy is the transcutaneous application of small electrical stimuli to the brain for treatment of selected psychiatric disorders like major depression. The tonic-clonic convulsions associated with electroconvulsive therapy can result in injuries such as limb fractures and compression fractures of vertebral bodies. The introduction of anesthesia, especially neuromuscular blockade, can mitigate tonic-clonic motor activity and reduce the physiologic trauma associated with uncontrolled tetanic muscle contractions.[216] Succinylcholine is commonly used as a NMBD in these patients, and its use is associated with well-known unwanted side effects.[216] Rocuronium has similar efficacy as succinylcholine in electroconvulsive therapy, making it an appropriate alternative to succinylcholine.[217] However, the increased doses of rocuronium required to decrease the onset time are associated with a prolonged duration of neuromuscular blockade. Several reports have evaluated the use of sugammadex in electroconvulsive therapy. These investigations demonstrated that sugammadex produced a complete and rapid reversal of neuromuscular blockade induced by rocuronium, without signs of residual blockade or other safety concerns.[217-220] Therefore the combination of rocuronium and sugammadex may be an alternative to succinylcholine for electroconvulsive therapy. However, the required dose of sugammadex in this clinical situation is not well established.

Historically, an important strategy in anesthesia has been to ensure that neuromuscular blockade is sufficiently recovered to achieve adequate antagonism by neostigmine. Having an intense neuromuscular blockade at the end of surgery would more likely result in residual blockade. With the availability of sugammadex, a profound, or deep, neuromuscular blockade has been recommended for the entire duration of laparoscopy. A profound neuromuscular blockade increases surgical space with smaller pressures for the pneumoperitoneum.[221] It is even possible that reducing insufflation pressures may improve patient outcomes.[221] Furthermore, Staehr-Rye and associates[222] have postulated that a deep or profound neuromuscular blockade is associated with more optimal surgical conditions, which leads to less postoperative pain and nausea and vomiting. A recent review and metaanalysis has shown that deep neuromuscular blockade during laparoscopic surgical procedures allows lower insufflation pressure, thereby improving surgical conditions and reducing postoperative pain.[223] Sugammadex, at doses of 2 to 8 mg/kg, was given to reverse the blockade when the TOF ratio was less than 0.90.

A recently published report describes the clinical experience in Japan.[224] Notably, although neuromuscular blockade was not routinely monitored intraoperatively, the TOF ratio was determined after tracheal extubation. A total of 249 patients were studied in three separate groups. Patients with spontaneous recovery ($n = 23$) were compared with patients being reversed with either neostigmine ($n = 109$) or sugammadex 2.7 mg/kg ($n = 117$). Although the sugammadex group had the least frequent incidence of residual neuromuscular blockade, all three groups had a surprisingly frequent incidence of residual neuromuscular blockade.[224]

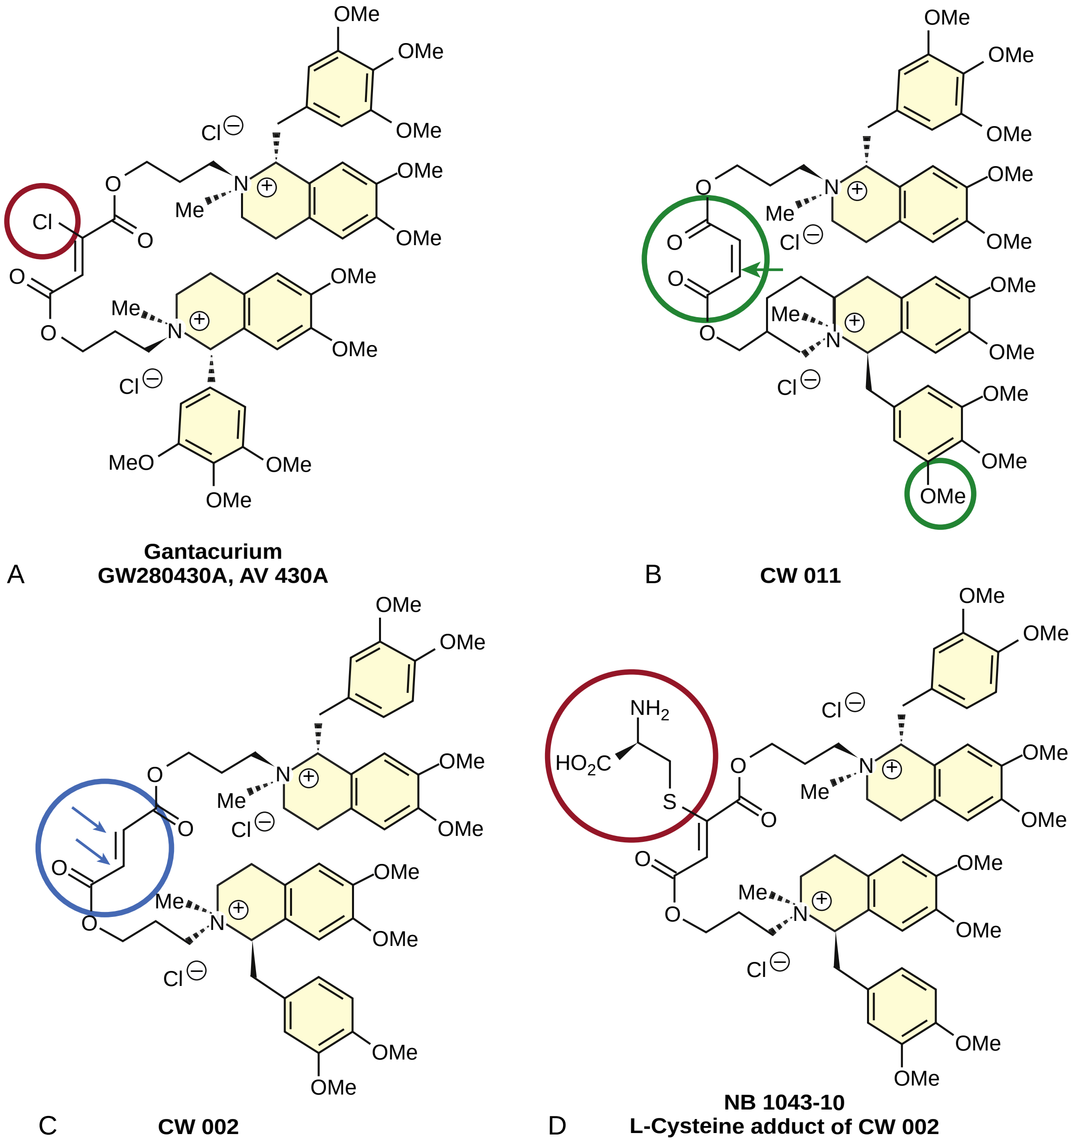
A scholarly editorial written by Naguib and associates[225] placed prime emphasis on the dose of sugammadex used for reversal in combination with the lack of neuromuscular monitoring. Although proper monitoring is strongly advisable, an adequate dose of sugammadex is under current debate. Although the reversal effect of neostigmine is not improved by increasing the dose above the recommended dose interval, there are strong reasons to believe that sugammadex in doses larger than 2.7 mg/kg would be more effective for reversal. Others argue that a dose of sugammadex larger than 2.0 mg/kg would not be necessary if proper monitoring were used. Of course, another possibility exists. It would seem that a larger dose of sugammadex plus neuromuscular monitoring would be ideal.

In conclusion, sugammadex provides a novel concept in reversal of neuromuscular blockade. Although the expense of sugammadex continues to be an important factor that may limit its use, many institutions currently use sugammadex for routine reversal of neuromuscular blockade. We speculate whether, in the future, larger doses of sugammadex will likely be used and whether routine neuromuscular monitoring will finally be mandatory in anesthetic practice among countries worldwide.

CYSTEINE REVERSAL OF FUMARATE NEUROMUSCULAR BLOCKING DRUGS

A new class of nondepolarizing NMBDs called fumarates has been recently developed. These NMBDs are olefinic (double-bonded) isoquinolinium diester compounds that differ from symmetric benzylisoquinolines such as mivacurium in their unique method of inactivation. The developed drugs (gantacurium [GW280430A, AV430A], CW002, and CW011) bind to L-cysteine to form less active degradation products (Fig. 28.23). The administration of L-cysteine can rapidly inactivate fumarate compounds and reverse neuromuscular blockade.

Gantacurium is an asymmetric α-chlorofumarate that was developed to be a replacement for succinylcholine.[226] Gantacurium has a rapid onset and short duration of effect. The brief duration of gantacurium is primarily due to rapid reaction and subsequent inactivation of the drug with free cysteine in the plasma. The process of adduction of cysteine to gantacurium occurs at the central fumarate double bond. The adduction changes the stereochemistry of gantacurium so that it can no longer bind to the nAChR at the neuromuscular junction. Degradation also occurs through a slower secondary route (pH-sensitive ester hydrolysis) that yields two products without neuromuscular blocking properties.[226,227] CW 002 (a symmetrical fumarate) and CW 011 (an asymmetric maleate) are investigational NMBDs with no halogen (chlorine) substitution at the central double-bonded carbons. The absence of chlorine results in a slower adduction with cysteine; the inactivation of CW 002 and CW 011 is slower than gantacurium, resulting in a duration of action consistent with an intermediate-acting NMBD.



A Gantacurium GW280430A, AV 430A

B CW 011

C CW 002

D NB 1043-10 L-Cysteine adduct of CW 002

Fig. 28.23 The chemical formulas of gantacurium (A), CW 011 (B), and CW 002 (C). Chemical features are as follows. Chlorine substitution *(red circle)* on the olefinic double bond of gantacurium, a chlorofumarate, is designed to accelerate the L-cysteine adduction reaction. The fumarate CW 002 is symmetrical with no halogen (chlorine) substitutions and undergoes L-cysteine adduction more slowly than gantacurium, at either olefinic carbon *(blue arrows)*, enabled by the adjacent α-carboxyl (ester) groups. The maleate CW 011 is asymmetric in that one isoquinolinium group contains an extra methoxy substitution *(green circle)*. This may reduce access of L-cysteine to the olefin *(green arrow)* and may decrease the rate of the adduction reaction. The chemical formula of NB 1043-10, the L-cysteine adduct of CW 002, is also shown (D). The L-cysteine adduction is highlighted by the *red circle.* (From Savarese JJ, McGilvra JD, Sunaga H, et al. Rapid chemical antagonism of neuromuscular blockade by l-cysteine adduction to and inactivation of the olefinic (double-bonded) isoquinolinium diester compounds gantacurium (AV430A), CW 002, and CW 011. *Anesthesiology*. 2010;113:58–73.)

Cysteine is a nonessential endogenous amino acid derived from one molecule of serine and one molecule of methionine. It is composed of L- and D-enantiomers. L-Cysteine is a normal building block of protein and is a conditionally essential amino acid in infants.[228] Several therapeutic applications of cysteine in medicine are common. It is often added to total parenteral nutrition solutions for pediatric patients in doses of approximately 80 mg/kg/day. An acetylated derivative of cysteine (*N*-acetyl L-cysteine) is approved for use in the treatment of acute acetaminophen toxicity. In the doses used clinically for these applications, there does not appear to be obvious toxicity. L-Cysteine has also been studied for reversal of the neuromuscular blockade for fumarate NMBDs. Several laboratory investigations have attempted to define the L-cysteine dose necessary to effectively reverse gantacurium, CW 002, and CW 011 neuromuscular blockade.

The first of the fumarate NMBDs studied was gantacurium. In monkeys, the total duration of action was one half to one third that of mivacurium at equipotent doses; at three times the ED$_{95}$ doses, the time until 95% twitch recovery was 8.5 ± 0.5 minutes versus 22.0 ± 2.6 minutes, respectively.[227] The administration of edrophonium 0.5 mg/kg accelerated the recovery of blockade. In a human volunteer trial, the time from administration of 0.40 mg/kg of gantacurium (2 × ED$_{95}$) until a TOF ratio 0.90 or greater was achieved was studied during spontaneous recovery or reversal with edrophonium 0.5 mg/kg.[229] Mean recovery time was significantly more rapid in the reversal group (3.8 minutes) compared with the spontaneous recovery group (14.3 minutes). The reversal of gantacurium with cysteine was investigated in monkeys.[228] A bolus of L-cysteine (10 mg/kg) given 1 minute after gantacurium reduced duration from 10.4 ± 3.1 minutes (spontaneous recovery) to 3.0 ± 1.0 minutes ($P < .001$). Antagonism of gantacurium was significantly faster at 1 minute with L-cysteine than edrophonium. These studies suggest that although gantacurium is a short-acting NMBD, recovery can be further enhanced by the administration of L-cysteine.

In contrast to gantacurium, CW 002 and CW 011 have a duration of action between a short-acting and intermediate-acting NMBD. In monkeys given four to five times the ED$_{95}$ of CW 002 and CW 011, the duration of blockade was three times longer than gantacurium (28.1 and 33.3 minutes vs. 10.4 minutes), but only half the duration of cisatracurium.[228] The administration of neostigmine 1 minute after CW 002 did not accelerate neuromuscular recovery. Immediate reversal of CW 002 with cysteine (50 mg/kg), however, was highly effective in antagonizing neuromuscular blockade (95% of baseline twitch height within 2.2 ± 0.3 minutes and to a TOF ratio of 100% 1–2 minutes later) (Fig. 28.24).[228] Similar findings were observed with CW 011 using this model. Larger doses of L-cysteine were needed to optimally reverse CW 002 and CW 011 (50 mg/kg) compared with gantacurium (10 mg/kg); this is likely related to the slower rate of adduction of L-cysteine to these compounds, as well as the greater potency of CW 002 and CW 011. L-Cysteine reversal of CW 002 has also been investigated in a dog model given a dose of 9 × ED$_{95}$.[230] L-Cysteine (50 mg/kg) reduced the median duration of blockade from 70 minutes (spontaneous recovery) to less than 5 minutes. Doses of up to 200 mg/kg produced minimal hemodynamic changes and resulted in no anatomic, biochemical, or histologic evidence of organ toxicity.

In summary, fumarates are a new class of NMBDs that are inactivated primarily via adduction of cysteine to the double

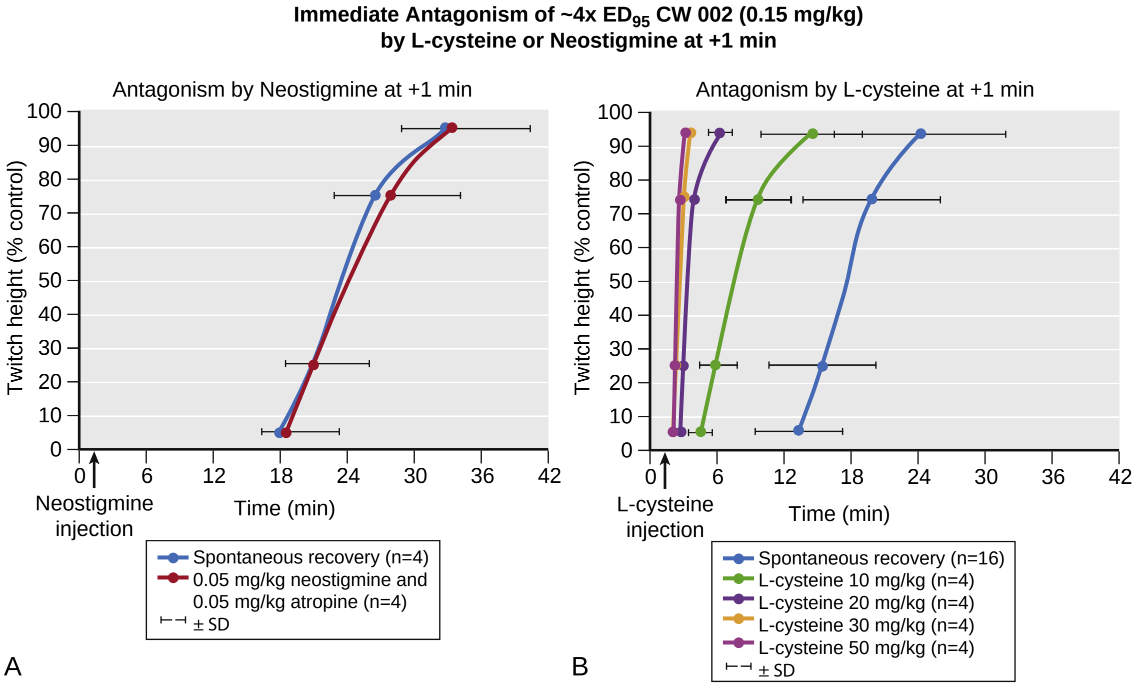


Fig. 28.24 Immediate antagonism of CW 002 blockade 1 minute after CW 002 dosage of 0.15 mg/kg, or ≈4 × ED$_{95}$, injected at $t = 0$. Neostigmine (0.05 mg/kg + atropine 0.05 mg/kg) or L-cysteine (10, 20, 30, or 50 mg/kg) was given at +1 min. Neostigmine did not shorten recovery (A), whereas L-cysteine produced a dose-related acceleration of recovery (B), peaking at 50 mg/kg. Data were taken from anesthetized rhesus monkeys. (From Savarese JJ, McGilvra JD, Sunaga H, et al. Rapid chemical antagonism of neuromuscular blockade by l-cysteine adduction to and inactivation of the olefinic (double-bonded) isoquinolinium diester compounds gantacurium (AV430A), CW 002, and CW 011. *Anesthesiology*. 2010;113:58–73.)

bond of the compounds, resulting in breakdown products that do not bind to the neuromuscular junction. Initial laboratory studies have shown that the administration of exogenous L-cysteine results in complete reversal of deep neuromuscular blockade within 2 to 3 minutes. These studies suggest that chemical antagonism of fumarate NMBDs will allow clinicians to rapidly and completely antagonize neuromuscular blockade, even when large doses of an NMBD have been recently administered. Early clinical trials in human volunteers have examined the pharmacology of gantacurium, and investigations of CW 002 in volunteers are currently ongoing. The optimal dose of L-cysteine is 50 mg/kg in an animal model. The dosing of L-cysteine needed to reverse the effects of gantacurium, CW 002, and CW 011 in humans has not been established. Additional investigations are also needed to determine whether large doses of cysteine produce adverse effects in humans. If future studies are consistent with these early findings, fumarate NMBDs may allow clinicians to maintain profound neuromuscular blockade throughout the surgical procedure with little risk of postoperative residual paralysis.

29 Local Anesthetics

PHILIPP LIRK and CHARLES B. BERDE

KEY POINTS

- Local anesthetics block voltage-gated sodium channels and thereby interrupt initiation and propagation of impulses in axons, but they have a wide variety of other biologic actions, desirable and undesirable.
- Currently available local anesthetics are of two chemical classes: aminoesters and aminoamides.
- The low potency and lack of specificity of available local anesthetics are due in part to the very weak structural constraints at their binding site on the sodium channel. Most of their features derive from the requirement for high solubility, rapidly reversible protonation, and rapid diffusion in both aqueous environments and in the lipid phases of biologic membranes.
- Reversible protonation of the tertiary amine group tends to make local anesthetics less charged at more basic pH and more charged at neutral or acidic pH; the neutral base forms are more soluble in lipid environments, whereas the charged acid forms, the more potent species, are more soluble in aqueous environments.
- Aminoesters are metabolized primarily by plasma esterases, and aminoamides are metabolized primarily by hepatic cytochrome P450-linked enzymes.
- The principal systemic toxicities of local anesthetics involve the heart (including atrioventricular conduction block, arrhythmias, myocardial depression, and cardiac arrest) and the brain (including agitation, lethargy, seizures, and generalized central nervous system depression). Hypoxemia and acidosis exacerbate these toxicities. Resuscitation after bupivacaine overdose is particularly difficult. Therefore prevention of intravascular injection or overdose is crucial, and major nerve blockade should involve incremental, fractionated dosing. Ultrasound can reduce the incidence of systemic toxicity and Intralipid can help in the resuscitation.
- Local anesthetics are directly toxic to nerve at the concentrations supplied in commercial solutions. Intraneural concentrations during regional anesthesia are generally (but not always) below a threshold for toxicity because of spread of solutions through tissues and diffusion gradients from injection sites into nerve. Injection into a constrained tissue space increases the risk for local toxicity.
- Optimal use of local anesthetics in regional anesthesia requires an understanding of (1) the individual patient's clinical situation; (2) the location, intensity, and duration of regional anesthesia and analgesia required; (3) anatomic factors affecting deposition of drug near nerves; (4) proper drug selection and dosing; and (5) ongoing assessment of clinical effects after administration of a local anesthetic.
- Single-stereoisomer (as opposed to a racemic mixture) formulations have been developed in an effort to reduce systemic toxicity and improve sensory selectivity but true sensory selectivity has not been achieved with drugs currently available.
- The most important research avenues to improve local anesthetic action are slow release formulations, targeting of specific sodium channel subtypes, and targeting of nociceptive fibers.

Local anesthesia results from the blockade of nerve impulses to abolish sensation. All currently available, clinically useful agents are either aminoesters or aminoamides. These drugs, when applied in sufficient concentration at the site of action, prevent conduction of electrical impulses by the membranes of nerve and muscle. In addition to blockade of impulses, local anesthetics can inhibit various receptors, enhance release of glutamate, and depress the activity of certain intracellular signaling pathways. When local anesthetic agents are given systemically, the functions of cardiac, skeletal, and smooth muscle, as well as transmission of impulses in the central and peripheral nervous systems and within the specialized conducting system of the heart, may all be altered. Local anesthetics may abolish sensation in various parts of the body by topical application, injection near peripheral nerve endings and major nerve trunks, or instillation within the epidural or subarachnoid spaces. Toxicity may be local or systemic. The central nervous and cardiovascular systems are most commonly involved in acute clinical toxicity.

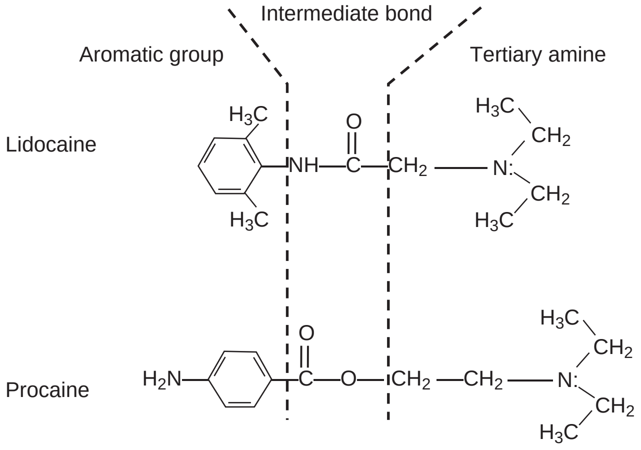

Fig. 29.1 Structures of two local anesthetics: the aminoamide lidocaine and the aminoester procaine. In both drugs, a hydrophobic aromatic group is joined to a more hydrophilic base, the tertiary amine, by an intermediate amide or ester bond.

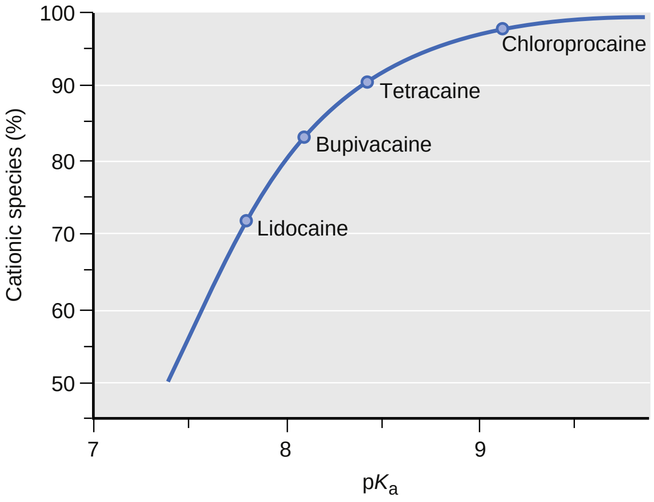

Fig. 29.2 Fraction of local anesthetic in the protonated, cationic form of an aqueous solution at physiologic pH (7.4) as a function of the pK_a of the drug. Lidocaine, the drug with the lowest pK_a, has the smallest fraction of its molecules protonated, the largest in the neutral form, and vice versa for chloroprocaine, the local anesthetic with the highest pK_a. Individual drug molecules become protonated and deprotonated in thousandths of a second in solution.

Basic Pharmacology

CHEMISTRY

The Local Anesthetic Molecule

The typical local anesthetic molecule, exemplified by lidocaine and procaine (Fig. 29.1), contains a tertiary amine attached to a substituted aromatic ring by an intermediate chain that almost always contains either an ester (see Fig. 29.1) or an amide linkage (Fig. 29.2).

Local anesthetics may therefore be classified as aminoester or aminoamide compounds. The aromatic ring system gives a lipophilic (membrane-liking) character to its portion of the molecule, whereas the tertiary amine end is relatively hydrophilic, particularly since it is partially protonated and thus bears some positive charge in the physiologic pH range (see Fig. 29.2). The structures of commonly administered local anesthetics are given in Table 29.1 and their physicochemical properties in Table 29.2.

STRUCTURE-ACTIVITY RELATIONSHIPS AND PHYSICOCHEMICAL PROPERTIES

The intrinsic potency and duration of action of local anesthetics are clearly dependent on certain features of the molecule.

Lipophilic-Hydrophilic Balance

The lipophilic versus hydrophilic character of a local anesthetic depends on the size of alkyl substituents on or near the tertiary amine and on the aromatic ring. “Lipophilicity” expresses the tendency of a compound to associate with membrane lipids, a property usually approximated by equilibrium partitioning into a hydrophobic solvent such as octanol.[1] Although octanol-buffer partition coefficients are comparable to membrane-buffer partition coefficients for the uncharged species of local anesthetics, they severely underestimate membrane partitioning for the charged, protonated species, octanol being a poor model for the polar regions near the membrane surface where local anesthetics are concentrated.[2] Here we use the term “hydrophobicity,” expressed as octanol-buffer partitioning, to describe a physicochemical property of local anesthetics.

Compounds with a more hydrophobic nature are obtained by increasing the size of the alkyl substituents. These agents are more potent and produce longer-lasting blocks than their less hydrophobic congeners do.[3-5] For example, etidocaine, which has three more carbon atoms in the amine end of the molecule than lidocaine, is four times as potent and five times as long lasting when compared in the isolated sciatic nerve.

Hydrogen Ion Concentration

Local anesthetics in solution exist in a very rapid chemical equilibrium between the basic uncharged form (B) and the charged cationic form (BH^+). At a certain hydrogen ion concentration ($\log_{10}{}^{-1}$ [$-$pH]) specific for each drug, the concentration of local anesthetic base in solution is equal to the concentration of charged cation. The logarithm of this hydrogen ion concentration is called pK_a. The relationship is defined by

$$\frac{[BH^{+}]}{[B]} = 10\ pK_a - pH$$

pK_a values of local anesthetic agents in aqueous solution are listed in Table 29.2. The tendency to be protonated also depends on environmental factors, such as temperature and ionic strength, and on the medium surrounding the drug. In the relatively apolar milieu of a membrane, the average pK_a of local anesthetics is lower than in solution. This is chemically equivalent to saying that the membrane concentrates the base form of the local anesthetic

TABLE 29.1 Representative Local Anesthetics in Common Clinical Use

Generic* and Common Proprietary Names	Chemical Structure	Approximate Year of Initial Clinical Use	Main Anesthetic Use	Representative Commercial Preparation
Cocaine		1884	Topical	40-mg/mL solution
Benzocaine (Americaine)		1900	Topical	200 mg/mL
Procaine (Novocain)		1905	Topical Infiltration Spinal	200 mg/mL 10- and 20-mg/mL solutions 100-mg/mL solution
Dibucaine (Nupercaine)		1929	Spinal	0.667-, 2.5-, and 5-mg/mL solutions
Tetracaine (Pontocaine)		1930	Spinal	Niphanoid crystals—20- and 10-mg/mL solutions
Lidocaine (Xylocaine)		1948	Infiltration Peripheral nerve blockade Epidural Spinal Topical Topical	5- and 10-mg/mL solutions 10-, 15-, and 20-mg/mL solutions 10-, 15-, and 20-mg/mL solutions 50-mg/mL solution 20-mg/mL jelly, viscous 25- and 50-mg/mL ointment
Chloroprocaine (Nesacaine)		1955	Infiltration Peripheral nerve blockade Epidural	10-mg/mL solution 10- and 20-mg/mL solutions 20- and 30-mg/mL solutions
Mepivacaine (Carbocaine)		1957	Infiltration Peripheral nerve blockade Epidural	10-mg/mL solution 10- and 20-mg/mL solutions 10-, 15-, and 20-mg/mL solutions
Prilocaine (Citanest)		1960	Infiltration Peripheral nerve blockade Epidural	10- and 20-mg/mL solutions 10-, 20-, and 30-mg/mL solutions 10-, 20-, and 30-mg/mL solutions
